cap which exhibits well-defined vertical striations. Columnar epithelium line nearly the whole gastro-intestinal tract and its glands, the greater part of the male urethra, the ductus deferens, the tubules and ducts of the prostate, the bulbo-urethral glands of Cowper, and the vestibular glands of Bartholin. In a modified form it also covers the ovary.

Fig. 5.—Goblet cells of a frog × 500.

Goblet- or *chalice-cells* are modified columnar cells. Each appears to be formed by an alteration in shape of a columnar cell (ciliated or otherwise) consequent on the formation of granules, which consist of a substance called *mucinogen*, in the interior of the cell. This distends the upper part of the cell, while the nucleus is pressed down towards its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane (fig. 5), the cell then assuming the shape of an open cup or chalice. A double centriole is found in the mucin-containing part of the goblet-cell. Cells of this kind are especially numerous in the mucous membrane of the stomach, and in the glands of the large intestine; they also occur in the epithelial covering of the villi of the small intestine and in that lining the respiratory tract (fig. 7).

The epithelium of glands is usually columnar, but in some the cells are

Fig. 8.—An isolated ciliated cell (semidiagrammatic).

cubical, in others they are polyhedral, in shape. The protoplasm shows a fine reticulum, which gives to the cells a granular appearance (fig. 6). Besides these protoplasmic 'granules,' gland-cells usually contain true granules which are the products of their own activity. These are in many cases zymogenic in nature, that is, they are, or contain, the precursors of enzymes or ferments.

Ciliated epithelium (fig. 7) is generally columnar in shape. It is distinguished by the presence of minute processes, resembling eyelashes (cilia), standing up from the free surface. The cilia (fig. 8), at their points of attachment to the free border of the cell, possess small nodular enlargements (*basal knobs* of Engelmann); from these knobs fine beaded filaments extend through the cell, and converge to a point near the fixed extremity. The basal knobs or particles have been supposed to be formed by division of the centriole. If the cells be examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells be separated, they will often be seen to be moved about in the field by this ciliary action.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Ciliated epithelium lines the respiratory tract from the nose downwards to the smallest ramifications of the bronchial tubes (except in the lower part of the pharynx and on the surfaces of the vocal folds); the tympanic cavity and auditory tube; the uterine tube and the cavity of the body of the uterus; the vasa efferentia, coni vasculosi and the first part of the ductus deferens; the ventricles of the brain and the central canal of the medulla spinalis.

FIG. 9.—Stratified epithelium from the œsophagus.

FIG. 10.—Epithelial cells from the oral cavity of man. × 350.

a. Superficial. *b.* From deeper layers. *c.* Cell with two nuclei.

Stratified epithelium (figs. 9 and 11) consists of several layers of cells. The cells vary greatly in shape; those of the deepest layer are for the most part columnar, and are placed vertically on the basement-membrane; above these are several layers of polyhedral cells, which as they approach the surface become more and more compressed, until the superficial ones are found to consist of flattened scales (fig. 10),

FIG. 11.—A section through the epidermis of the skin of the sole of the foot, stained with hæmatoxylin and van Gieson's stain. × 250.

which overlap one another so as to present an imbricated appearance. The epithelium of the skin, or epidermis, is peculiar in that it shows four distinct layers. The deep layer consists of columnar and polyhedral cells as in stratified squamous epithelium generally (stratum mucosum). In the next layer, or stratum granulosum, the cells are fusiform in section, and contain granules of a substance called *eleidin*. The third layer, or stratum lucidum, consists of cells in which the eleidin has undergone a transformation into a substance called *keratohyalin*; and the cells of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

most superficial layer (stratum corneum) are completely converted into a horny material, known as *keratin* (fig. 11).

The cells of the deeper layers of stratified squamous epithelium are called *prickle-cells*; they are not closely joined together by cement-substance, but are separated from each other by intercellular channels, between which are protoplasmic bridges containing fine fibrils which connect the adjacent cells with each other. When a cell is isolated, it appears to be covered over with a number of short spines, in consequence of the bridges being broken through.

Stratified epithelium is found in the skin, in the conjunctiva, on the anterior surface of the cornea, and in the mucous membrane of the mouth, lower part of the pharynx, œsophagus, vagina and part of the cervix uteri.

FIG. 12.—Transitional epithelium.

Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are large and flattened, with depressions on their under surfaces to fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement-membrane. Between the tapering points of the cells of the second layer is a third variety of cells of smaller size than those of the other two layers (fig. 12). In the distended condition of the bladder the superficial cells are more flattened, and the pear-shaped cells are shorter and broader than they are when the bladder is contracted.

THE CONNECTIVE TISSUES

The term **connective tissue** includes a number of tissues which have a passive function, that of binding together or supporting the functionally active structures; they differ considerably from each other in appearance, but present many points of relationship, and are, moreover, developed from the same layer of the embryo, the mesoderm. They are divided into three great groups: (1) the connective tissues proper, (2) cartilage, and (3) bone.

The circulating fluids (although functionally different) are regarded by some histologists as a form of connective tissue, and are dealt with in this section.

THE CONNECTIVE TISSUES PROPER

Several varieties of connective tissue are recognised: (1) Areolar tissue. (2) White fibrous tissue. (3) Yellow elastic tissue. (4) Mucoid tissue. (5) Retiform tissue. They are all composed of a homogeneous matrix, in which are imbedded cells and fibres—the latter of two kinds, white, and yellow or elastic. The distinction between the different varieties depends upon the relative preponderance of one or other kind of fibre, of cells, or of matrix.

Areolar tissue (fig. 13) is so called because, when artificially distended with air or fluid, it exhibits intercommunicating areolæ or spaces. It is extensively distributed and its chief use is to bind parts together, though allowing, in virtue of its extensibility and elasticity, a considerable amount of movement to take place. It occurs as subcutaneous tissue, as the submucous coat in the digestive tract, and as subserous tissue. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. It is present in the interior of organs, binding together the lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles and nerves.

When areolar tissue is stretched it is seen to be made up of soft elastic threads, resembling spun silk, and interlacing in all directions. A thin layer, examined under the microscope, shows fibres and cells, imbedded in a homogeneous ground-substance or *matrix*.

The fibres form an irregular meshwork, and are of two kinds, white and yellow. The *white fibres* are exceedingly fine; they are colourless, homogeneous and transparent, and are arranged parallel to each other in bundles, which have a wavy

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

course. The individual fibres do not branch, but small bundles of them may leave one large bundle to join another. The *yellow* or *elastic fibres* have well-defined out-

FIG. 13.—Subcutaneous tissue from a young rabbit. Highly magnified. (From Sir Edward Sharpey Schafer's Essentials of Histology.)

c. c'. Lamellar cell. *f.* Fibrillated cell. *g.* Plasma-cell. *p.* Clasmatocytes.

lines, and are usually somewhat larger than the white fibres, varying in diameter from 1μ to 6μ.* They are pale yellow in colour, homogeneous in appearance, run a

FIG. 14.—Areolar tissue of a rabbit, silvered. × 255. Ground-substance stained, cells unstained.

comparatively straight course, branch, and anastomose freely with each other. When they are broken across, the ends tend to curl up. They also differ from the white fibres in staining a dark red colour with orcein.

* A micromillimetre (μ) is $\frac{1}{1000}$ of a millimetre or $\frac{1}{25400}$ of an inch.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The cells of areolar tissue are of four principal kinds: (1) Flattened *lamellar cells*, may be either branched or unbranched. The branched lamellar cells are composed of clear protoplasm, with few granules, and contain oval nuclei; their processes may unite with those of neighbouring cells, so as to form a syncytium, as in the cornea. Occasionally a cell may be found which shows fibrillation of its protoplasm. Some observers believe such a condition to be a stage in the formation of the white fibres. The unbranched cells are joined edge to edge like the cells of an epithelium; the flattened cells lining the serous cavities are examples of this variety. (2) *Clasmatocytes* are large irregular cells characterised by the presence of granules or vacuoles in their protoplasm, and containing oval nuclei. (3) *Granule-cells* are ovoid or spheroidal in shape and contain basiphil granules. (4) *Plasma-cells* of Waldeyer are usually spheroidal in shape and distinguished by containing a vacuolated protoplasm; the vacuoles are filled with fluid, and the protoplasm between them is clear, with occasionally a few scattered basiphil granules.

In addition to these four types of cells, areolar tissue may contain *wandering cells*, i.e. leucocytes which have emigrated from the neighbouring vessels; in some instances, as in the chorioid coat of the eye, cells filled with granules of pigment (*pigment-cells*) are found.

The cells lie in spaces in the ground-substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light; this will colour the ground-substance and leave the cell-spaces unstained (fig. 14).

Adipose tissue.—In almost all parts of the body areolar tissue contains a variable quantity of adipose tissue or fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, of the penis and scrotum, of the labia minora; within the cavity of the cranium; and in the lungs, except near their

FIG. 15.—Adipose tissue, from the omentum. Stained with Sudan III. and hæmatoxylin. ×350.

roots. The distribution of adipose tissue is not uniform; in some parts it is in great abundance, as in the subcutaneous tissue, especially of the abdomen, around the kidneys, and in the mesentery and omentum. Lastly, fat enters largely into the formation of the marrow of bones.

Adipose tissue consists of *fat-cells*, lodged in the meshes of areolar tissue. Fat-cells (fig. 15) vary in size, the average diameter being about 50μ; each consists of an exceedingly delicate protoplasmic membrane, filled with fatty substance, which is liquid during life, but solidifies after death. They are round or spherical where they are not subjected to pressure; otherwise they are more or less polygonal.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A nucleus is always present under the cell-membrane and can be demonstrated by staining with hæmatoxylin; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognisable. The fat-cells are held together mainly by the network of capillary blood-vessels which is distributed to them.

Fig. 16.—Development of fat. (Klein and Noble Smith.)

a. Minute artery. *v*. Minute vein. *c*. Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. *d*. The ground-substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

Chemically the oily material is composed of olein, palmitin, and stearin, which are glycerol esters of fatty acids. Sometimes fat-crystals form in the cells after death. By boiling the tissue in ether or strong alcohol, the fat may be extracted from the cells, leaving them empty and shrunken.

Fat first appears in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of connective tissue cells. Small droplets of oil are formed in the protoplasm, and these coalesce to produce a larger drop, which increases until it distends the cell, the remaining protoplasm and the nucleus being displaced towards the periphery (fig. 16).

White fibrous tissue is a true connecting structure, and serves three purposes in the animal economy. In the form of ligaments it binds bones together; in the form of tendons it connects muscles with bones or other structures; it constitutes investing or protecting membranes to various organs. Examples of such membranes are to be found in the muscular fasciæ or sheaths, the periosteum, and the perichondrium; the capsules of the various glands; the investing sheaths of the nerves (perineurium), and of various organs, as the penis and the eye.

Fig. 17.—White fibres. × 350.

Fig. 18.—Tendon of a rat's tail, stained with gold chloride, showing chains of cells between the tendon-bundles. × 250.

In white fibrous tissue, as its name implies, the white fibres (fig. 17) predominate; the matrix is apparent only as a cement-substance, yellow elastic fibres are comparatively few, while the tissue-cells are arranged in a special manner. It presents to the naked eye a silvery white glistening appearance; it is devoid of elasticity, and has only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence, a bone with which it is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

connected may fracture before the fibrous tissue gives way. In ligaments and tendons the bundles of fibres run parallel with each other; in membranes they intersect one another. The cells found in white fibrous tissue are often called 'tendon-cells.' They are situated on the surfaces of groups of fibres, and are arranged in rows, each cell being separated from its neighbours by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (fig. 18). The tendon-cells have

FIG. 19.—A transverse section through a tendon of a rat. × 120.

wing-like processes which pass between the bundles of fibres, giving a stellate appearance in transverse section (fig. 19). When viewed from the side, the cell with its wings is quadrangular, and there may be the appearance of a vertical line on the body of the cell owing to the projection of a wing towards the eye of the observer (fig. 18). Upon the addition of acetic acid, white fibrous tissue swells up into a glassy-looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin, the white fibres being composed of *collagen*, which is regarded as the anhydride of gelatin.

Yellow elastic tissue.—In certain parts of the body a tissue is found which is of a yellowish colour, and possessed of great elasticity. It is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*; it may be regarded as a connective tissue in which the yellow elastic fibres have developed to the practical exclusion of the other elements. It is found in the ligamenta flava, in the vocal folds and conus elasticus of the larynx, in the mucous membrane of the trachea and bronchi, in the walls of the pulmonary air-vesicles, in the coats of the blood-vessels, especially the larger arteries, and to a very considerable extent in the hyothyreoid and stylohyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals (fig. 20). Where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding with the

FIG. 20.—Ligamentum nuchæ of the ox, stained with picrocarmine. × 280.

a. Longitudinal section. *b*. Transverse section.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

intervening spaces. This is found in the inner coat of the arteries, and to it the name of *fenestrated membrane* has been given by Henle. Yellow elastic fibres remain unaltered by acetic acid; chemically they are composed of the sclero-protein known as *elastin*.

Mucoid tissue exists in the 'jelly of Wharton,' which forms the bulk of the umbilical cord, but is also found in the fœtus, chiefly as a stage in the development of connective tissue. It consists of a matrix, largely made up of mucin, in which are nucleated cells with branching and anastomosing processes (fig. 21). Few fibres are seen in typical mucoid tissue, though at birth the umbilical cord shows a considerable development of fibres. In the adult the vitreous body of the eye is a persistent form of mucoid tissue, in which the fibres and cells are very few in number.

Retiform or reticular tissue (fig. 22) is found extensively in many parts of the body, constituting the framework of some organs and entering into the construction of many mucous membranes. It is a variety of connective tissue, in which the

FIG. 21.—Mucoid tissue from the umbilical cord of a human embryo of four months, stained with hæmatoxylin and eosin. × 255.

intercellular or ground-substance is, in a great measure, replaced by fluid. It is composed almost entirely of extremely fine bundles of white fibrous tissue, forming an intricate meshwork, and chemically it yields *gelatin* on boiling. The fibres are covered and concealed in places by flattened branched connective tissue-cells. In many situations the interstices of the network are filled with rounded lymph-corpuscles, and the tissue is then termed **lymphoid tissue.**

Basement-membranes consist of thin sheets of modified connective tissue, and are found underlying layers of epithelial cells, for example, in mucous membranes and secreting glands. They may be formed of cells or of condensed ground-substance. In the former case, flattened cells, which are modified connective tissue corpuscles, are united by their edges by means of cement-substance, which can be demonstrated by staining with silver nitrate; if the cells are unbranched, the membrane is continuous; if they are branched, the processes are united, and the membrane is fenestrated. The basement-membrane underlying the epithelium on the anterior surface of the cornea is composed of ground-substance.

Vessels and nerves of connective tissue.—The *blood-vessels* of connective tissue are very few—that is to say, few are supplied to the tissue itself, although many carrying blood to other structures may permeate one of its forms, the areolar tissue. In white fibrous tissue the blood-vessels usually run parallel to and between the longitudinal bundles, sending communicating branches across the bundles; in some forms, as in the periosteum and dura mater, they are fairly numerous. In

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

yellow elastic tissue, the blood-vessels also run between the fibres. *Lymphatic vessels* are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves.

FIG. 22.—Retiform and lymphoid tissue from a lymph-gland, stained with picrocarmine. × 255.

Nerves are found in white fibrous tissue, where they end in a special manner; but it is doubtful whether any nerves end in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Pigment.—Pigment is found in various parts of the body; most frequently in epithelial cells and in the cells of connective tissue. Pigmented *epithelial cells* form the external layer of the retina, and are present on the posterior surface of the iris, in the olfactory region of the nose, in the membranous labyrinth of the ear, in the deeper layers of the cuticle, and in the hairs. Pigment is abundantly present in the skin of the coloured races, but in the skin of white races it is well-marked only in the areolæ round the mammary papillæ and in irregular coloured patches. Pigmented *connective tissue-cells* are frequently met with in the lower vertebrates. In man they are found in the chorioid coat of the eye (fig. 23), and in the iris of all but the light blue eyes and the albino. The cells are usually large and branched, and are filled with brown or black granules, consisting of *melanin*. In the retina the processes of the cells extend between the rods and cones; when the eye is exposed to light the pigment-granules extend into these processes, and under the influence of darkness they are withdrawn into the body of the cell.

FIG. 23.—Pigment-cells from the chorioid coat of the eyeball.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The pigment-granules are of very small size and are closely packed within the cells, but do not invade the nuclei. Occasionally they are yellow, and when occurring in the cells of the cuticle constitute 'freckles.' In the retina another variety of pigment occurs, known as *rhodopsin* or *visual purple*, which is bleached on exposure to light.

Applied Anatomy.—Congenital absence of pigment from the skin and other tissues constitutes the condition known as albinism. Localised patches of skin from which pigment is absent are found in leucoderma; linear white streaks may result from old scars or from overdistension of the skin, particularly that over the abdomen following pregnancy or ascites. A congenital excessive pigmentation may be general, or may occur locally in the form of dark brown or black nævi (moles). Pigmented patches occasionally follow the continued action of local irritants, and a general swarthiness may result from excessive exposure to the sun, particularly in association with uncleanliness (vagabondinismus). A rare form of general pigmentation ensues on the prolonged administration of salts of silver or of arsenic. Disorders of the endocrine organs may be associated with much discoloration of the skin; this is particularly noticeable in Addison's disease (suprarenal glands) where the pigmentation occurs mostly on the face, exposed parts of the neck, backs of hands, axillary and umbilical regions, genital organs, and medial surfaces of the thighs, but invades also the buccal and lingual mucous membranes. In pregnancy and in some uterine disorders patches of discoloration may be seen round the nipples, over the linea alba, and on the face. Many chronic wasting diseases are accompanied by peculiar colorations of the skin, notably cancer and phthisis; in the latter there may be much deepening of the tint over the zygomatic bones and round the orbits.

Development of connective tissue.—Connective tissue is developed from cells of the mesoderm. These cells multiply and form a syncytium containing many nuclei. The ground-substance appears in spaces between the cells as an albuminous fluid. Later, granules are deposited in the ground-substance by the activity of the cells, and become fused to form the fibres of the tissue.

Cartilage

Cartilage is a non-vascular structure found in various parts of the body—in the joints, parietes of the thorax, trachea, bronchi, nose, and ears. In the fœtus,

Fig. 24.—Cartilage cells in the costal cartilage of a kitten, stained with picrocarmine. × 350.

at an early period, the greater part of the skeleton is cartilaginous; as this cartilage is afterwards replaced by bone, it is called *temporary*, in contradistinction to that which remains unossified and is called *permanent*.

Cartilage is divided, according to its minute structure, into *hyaline cartilage*, *white fibrocartilage*, and *yellow* or *elastic fibrocartilage*. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, formed entirely, or almost entirely, of cells, separated from each other by their capsules only, which in this kind of cartilage are extremely well marked. Cellular cartilage is found in the external ears of rats, mice, and some other animals, and it also forms a stage in the development of cartilage in human embryonic life.

CC-0. In Public Domain. Panini Kanya Maha Vidyalaya Collection.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Hyaline cartilage has a pearly bluish colour and consists of a gristly mass of a firm consistence, but of considerable elasticity. Except where it coats the articular ends of bones, it is covered by a fibrous membrane, the *perichondrium*, from the vessels of which it imbibes its nutritive fluids, being itself destitute of blood-vessels. It contains no nerves. If a thin slice be examined under the microscope, it is seen to consist of cells of a rounded or bluntly angular form, lying in spaces in a granular or almost homogeneous matrix (fig. 24). The cells are frequently arranged in groups of two or more, and, when this is so, they have generally straight outlines where they are in contact with each other, but are rounded in the rest of their circumference. They consist of clear translucent protoplasm in which fine interlacing filaments and minute granules are sometimes present; imbedded in the protoplasm are one or two round nuclei, having the usual intranuclear network.

The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. The portion immediately surrounding each cell-space is often well-defined, and is further characterised by its affinity for basic dyes. It is known as the *capsule* of the space. The matrix of hyaline cartilage, and especially that of the articular variety, can be broken up into fine fibrils after prolonged maceration. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the cell-spaces with each other and with the lymphatics of the perichondrium, and that in this way nutrient fluid obtains access to the cartilage-cells.

FIG. 25.—A vertical section through articular cartilage.

Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety, but they present differences in the size, shape, and arrangement of their cells.

Articular cartilage (fig. 25) shows no tendency to ossification; its matrix is finely granular, and its cells are flattened and disposed parallel to the surface in the superficial part of the cartilage, while nearer to the bone they are oval and are arranged in vertical rows. It has a tendency to split in a vertical direction. Its free surface is not covered by perichondrium, but the synovial stratum of the articular capsule can be traced over a small part of its circumference, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective tissue-cells of the synovial stratum. It forms a thin layer upon the joint-surfaces of the bones, and its elasticity enables it to break the force of concussions, while its smoothness gives ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, the reverse being the case on concave articular surfaces. It appears to derive its nutriment partly from the vessels of the synovial stratum of the joint-capsule and partly from those of the bone upon which it is implanted. The minute vessels of the spongy bone dilate and form arches as they approach the articular lamella, and then return into the substance of the bone.

In **costal cartilage** the cells and nuclei are large, and the matrix, which is usually homogeneous and transparent, has a tendency to fibrous striation, especially in old age (fig. 26). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears, at first sight, to be an exception to the statement that cartilage is non-vascular, but is not so really, for the vessels give no branches to the cartilage itself, and the channels may rather be looked upon as involutions of the perichondrium. The xiphoid process of the sternum and the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cartilages of the nose, larynx, and trachea (except the epiglottis and corniculate cartilages of the larynx, which are composed of elastic fibrocartilage) resemble the costal cartilages in microscopical characteristics. The arytænoid cartilage of the larynx shows a transition from hyaline cartilage at its base to elastic cartilage at the apex.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, their matrix becomes permeated by calcium salts. Calcification occurs frequently in the costal cartilages, and in the cartilages of the trachea, and may be succeeded by ossification.

FIG. 26.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. Highly magnified.

White fibrocartilage consists of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; the cells are roughly ovoid in shape, and are surrounded by concentrically striated areas of cartilage-matrix (fig. 27). The white fibrocartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

1. The *interarticular fibrocartilages* (*menisci*) are flattened fibrocartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints; the synovial stratum of the articular capsule covers their free surfaces. They are found in the temporomandibular, sternoclavicular, acromioclavicular, wrist- and knee-joints. Their uses are to obliterate the intervals between opposed surfaces in their various motions; to increase the depths of the articular surfaces

FIG. 27.—White fibrocartilage from the intervertebral fibrocartilage of a sheep, stained with borax-carmine. × 300.

and give ease to the gliding movements; they also increase the varieties of movement in a joint.

2. The *connecting fibrocartilages* are interposed between the bony surfaces of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

those joints which admit of only slight mobility, as between the bodies of th vertebræ. They form discs which are closely adherent to the opposed surface Each disc is composed of concentric layers of fibrous tissue, with cartilaginou laminæ interposed, the former tissue predominating towards the circumferenc the latter towards the centre.

3. The *circumferential fibrocartilages* consist of rims of fibrocartilage, whic surround the margins of some of the articular cavities, e.g. the glenoidal labru of the hip-joint and that of the shoulder-joint; they serve to deepen the articula cavities and to protect their edges.

4. The *stratiform fibrocartilages* form thin coatings to osseous grooves throug which the tendons of certain muscles glide.

Small masses of fibrocartilage are also developed in the tendons of some muscle where they glide over bones, as in the tendons of the Peronæus longus and Tibialis posterior.

Yellow or elastic fibrocartilage is found in the ears, the corniculate cartilages of the larynx, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded by a network of yellow elastic fibres, branching and anastomosing in all directions, except immediately around the cells, where there is a variable amount of hyaline substance (fig. 28). The fibres resemble those of yellow elastic tissue, not only in appearance, and in being unaffected by acetic acid, but also in their affinity for orcein; according to Rollett their continuity with the elastic fibres of the neighbouring tissue is demonstrable.

FIG. 28.—Yellow or elastic fibrocartilage from th epiglottis of a cat. × 250.

The distinguishing feature of cartilage, chemically, is that it yields on boiling a substance called *chondrin*, a mixture of gelatin with mucinoid substances, chief among which is a compound termed *chondromucoid*.

BONE

Structure and physical properties.—Bone is one of the hardest structures o the animal body; it possesses also a certain degree of toughness and elasticity. Its colour, in a fresh state, is pinkish white externally, and deep red within. In section it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *substantia compacta*; the other consists of slender fibres and lamellæ, which join to form a reticular structure; this is called *substantia spongiosa* or, from its resemblance to lattice work, *cancellous tissue*. The compact substance is always placed on the exterior of the bone, the spongy in the interior. The relative quantities of these vary in different bones and in different parts of the same bone, according as strength or lightness is requisite. Close examination of the compact substance shows it to be extremely porous, so that the difference between it and the spongy substance depends merely upon the relative amount of solid matter and the size and number of spaces in each; in the compact substance the spaces are small and the solid matter abundant, while in the spongy substance the spaces are large and the solid matter small in quantity.

During life, bone is permeated by vessels, and enclosed, except where it is coated with articular cartilage, in a fibrous membrane, the *periosteum*, by means of which many of these vessels reach the bone. If the periosteum be stripped from the surface of the living bone, small bleeding points are seen which mark the entrance of the periosteal vessels, and on section every part of the bone exudes blood from

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

he minute vessels which ramify in it. In the interior of the long bones of the imbs is a cylindrical cavity (*cavum medullare*) filled with *medulla ossium* or *marrow*, nd lined with a membrane composed of highly vascular areolar tissue, called the *nedullary membrane* or *internal periosteum*.

The **periosteum** adheres to the surfaces of the bones in nearly every part, but not to the cartilage covering their articular surfaces. When strong tendons or igaments are attached to a bone, the periosteum is incorporated with them. It onsists of two layers closely united together, the outer formed chiefly of white ibrous tissue, containing occasionally a few fat-cells; the inner, of elastic fibres of he finer kind, forming dense membranous networks, which can be again separated nto several layers. In young bones the periosteum is thick and very vascular, nd is intimately connected at either end of the bone with the epiphysial cartilage, but less closely with the body of the bone, from which it is separated by a layer of oft tissue, containing a number of granular corpuscles or 'osteoblasts,' by which ssification proceeds on the exterior of the young bone. Later in life the periosteum s thinner and less vascular, and the osteoblasts are represented by a single layer of lattened cells on its deep surface. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of one to exfoliation or necrosis when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also e demonstrated in the periosteum.

The **medulla ossium** or **marrow** not only fills up the cylindrical cavities in the odies of the long bones, but also occupies the spaces of the cancellous tissue and xtends into the larger Haversian canals. It differs in composition in different ones. In the bodies of the long bones the marrow is of a *yellow* colour (*medulla ssium flava*), and consists of a basis of connective tissue supporting numerous lood-vessels and cells, most of which are fat-cells, but some are 'marrow-cells,'

FIG. 29.—Human bone-marrow. Highly magnified.

such as occur in the red marrow. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs, the marrow is of a *red* colour (*medulla ossium rubra*).* Red marrow consists of a small quantity of connective tissue, blood-vessels, and numerous cells (fig. 29), a few of which are fat-cells but the great majority are spherical,

* Alfred Pinney (*Lancet*, Sept. 9th, 1922, p. 572) has investigated the naked-eye anatomy of the bone marrow in 1700 post-mortem cases, and concludes that all the bones, except those of the cranium, contain red marrow until puberty.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

nucleated cells, termed *myelocytes* or *marrow-cells*. The myelocytes resemble the leucocytes of the blood, and like them are amœboid; they contain granules, either oxyphil, basiphil or neutrophil in reaction. A number of eosinophil cells and a few basiphil cells are also present. Amongst the myelocytes may be seen smaller nucleated cells, of a yellowish colour; these are the *erythroblasts* or *normoblasts* from which the red corpuscles of the blood are derived by the disappearance of the nuclei. Giant-cells (*myeloplaxes* or *megakaryocytes*) similar to the osteoclasts described in connexion with the development of bone are also found in red marrow. In post-natal life the red marrow is the chief seat of the formation of the corpuscles of the blood.

Vessels and nerves of bone.—The *blood-vessels* of bone are very numerous. Those of the compact substance are derived from a close network of vessels in the periosteum. Vessels pass from this network into the minute orifices in the compact substance, and run in the Haversian canals which traverse it. The spongy substance is supplied in a similar way by larger vessels, which perforate the outer compact substance, and are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces; some of these give passage to arteries, but the greater number transmit veins from the spongy substance. The marrow of a long bone is supplied by an artery which enters the bone at the nutrient foramen (*foramen nutricium*). The *nutrient* artery, usually accompanied by one or two veins, sends branches upwards and downwards, which ramify in the medullary membrane, and give twigs to the adjoining Haversian canals. The ramifications of this vessel anastomose with the arteries of the spongy and compact substances. In most of the flat, and in many of the short, bones there are one or more large apertures for the transmission of nutrient vessels. Veins emerge from the long bones as follows:—(1) one or two accompany the nutrient artery; (2) numerous large and small veins emerge near the articular extremities; (3) many small veins pass out of the compact substance. In the flat cranial bones the veins are large and run in tortuous canals in the diploic tissue, the walls of the canals being formed by thin lamellæ of bone, perforated here and there for the passage of branches from the adjacent diploë. The same condition is found in all spongy substance, the veins being enclosed and supported by osseous material, and having exceedingly thin coats. When a bone is divided, the vessels remain open, and do not contract in the canals in which they are contained. *Lymphatic vessels*, which communicate with those in the periosteum, are found in the Haversian canals. *Nerves* are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said to be most numerous in the articular extremities of the long bones, in the vertebræ, and in the larger flat bones.

circular districts, each consisting of a central hole surrounded by a number of concentric rings. These districts are termed *Haversian systems*; the central hole is a *Haversian canal*, and the rings are *lamellæ* of bony tissue arranged concentrically around the central canal. Between these lamellæ are a number of small spaces termed *lacunæ*, which are connected with each other and with the central Haversian canal by many fine radiating channels called *canaliculi*. Filling in the irregular intervals between these circular districts are *interstitial* lamellæ, with their lacunæ and canaliculi, running in various directions, but more or less parallel with the surface (fig. 30). Again, other lamellæ are found on the surface of the bone completely encircling it; they are termed *circumferential* or *primary* lamellæ, to distinguish them from those surrounding the Haversian canals, which are termed *secondary* lamellæ.

FIG. 31.—A longitudinal section of the body of the femur. × 100.

a. Haversian canals. *b*. Lacunæ seen from the side. *c*. Others seen from the surface in lamellæ which are cut horizontally.

In a longitudinal section it will be seen that the Haversian canals run parallel with the long axis of the bone but branch and communicate at short intervals (fig. 31). They vary considerably in size, but their average diameter is about 0·05 mm. The canals near the medullary cavity are larger than those near the surface of the bone. Each canal usually contains a minute artery and vein, a small quantity of delicate connective tissue, and some nerve-filaments; in the larger ones there are also lymphatic vessels, and cells with branching processes.

The *lamellæ* are thin plates of bony tissue. They may be stripped off as thin films from a piece of bone which has been macerated in dilute mineral acid. If one of these films be examined with a high power of the microscope, it will be found

FIG. 32.—The perforating fibres of a human parietal bone, decalcified. (H. Müller.) (From Quain's Elements of Anatomy, vol. ii. pt. i., Microscopic Anatomy.)

a. Perforating fibres *in situ*; *b*. Fibres drawn out of their sockets; *c*. Sockets.

to be composed of fine fibres identical with the white fibres of connective tissue. The matrix between the fibres is impregnated with lime-salts which the acid dissolves. The fibres are arranged in bundles, and fibres leave the bundles of one lamella to join those of adjacent lamellæ. In this way the fibres of one lamella usually form an acute

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

angle with those of the contiguous layer; in the Haversian systems, however, the fibres of adjacent lamellæ run at right angles to each other. In many places the various lamellæ are held together by tapering fibres, which run obliquely through them, pinning or bolting them together; these fibres were first described by Sharpey, and were named by him *perforating fibres* (fig. 32.)

The *lacunæ* are oblong spaces situated between the lamellæ, and each lacuna is occupied during life by a branched *bone-cell* (fig. 33), the processes from which extend into the canaliculi.

The *canaliculi* are minute channels, crossing the lamellæ and connecting the lacunæ of a Haversian system with one another, and with the Haversian canal. The canaliculi at the periphery of a Haversian system do not as a rule communicate with those of neighbouring systems, but form loops and return to their own lacunæ. Thus every part of a Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and distributed through the canaliculi and lacunæ.

The *bone-cells* occupy, but do not fill, the lacunæ. They are flattened nucleated branched cells, homologous with the lamellar cells of connective tissue; their branches pass into the canaliculi.

FIG. 33.—Nucleated bone-cells and their processes, contained in the bone-lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

In thin plates of bone Haversian canals are absent.

Chemical composition.—Bone consists of animal or organic, and mineral or inorganic, substances intimately combined.

The animal substance forms about 33 per cent. of the total weight,* and may be obtained by immersing a bone for a considerable time in dilute mineral acid which will dissolve the mineral matter. The bone retains its shape, but is now

FIG. 34.—A transverse section through a portion of the body of a human fibula, decalcified. × 250.

श्री धर्मदत्त वैद्य संग्रह
04584

perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. In a transverse section of such a softened bone (fig. 34), the arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi can be recognised.

* H. E. Radasch (*Proceedings of the American Association of Anatomists, Anatomical Record*, vol. 21) states that in [illegible] organic substance averages 10·75 per cent.

The mineral substance may be obtained by calcination which destroys the animal matter. The bone retains its original form, but is white and brittle, has lost about one-third of its original weight, and crumbles under the slightest force. The mineral substance, composed chiefly of calcium phosphate, forms about 66·7 per cent. of the weight of the bone; it confers on bone its hardness and rigidity, while the animal matter (*ossein*) determines its resiliency and tenacity.

Ossification.—Some bones, such as those of the roof and sides of the skull, are preceded by membrane, but most bones are preceded by rods or masses of cartilage. Hence two kinds of ossification are described; the *intramembranous* and the *intracartilaginous*.

Intramembranous ossification.—The membrane which occupies the place of the future bone is of the nature of connective tissue, and ultimately forms the

FIG. 35.—A part of the growing edge of the developing parietal bone of a fœtal cat. (From Quain's Elements of Anatomy: Sir Edward Sharpey Schafer.)

periosteum; it is composed of fibres and granular cells in a matrix richly supplied with blood-vessels. The peripheral portion is more fibrous, while in the central portion the cells or *osteoblasts* predominate. At the outset of the process of bone formation a little network of fibres radiates from the centre of ossification. These rays consist at their growing points of a network of fine clear fibres and granular corpuscles with an intervening ground-substance (fig. 35). The fibres are termed *osteogenetic* fibres, and differ little from those of white fibrous tissue. The membrane assumes a dark and granular appearance from the deposition of calcareous granules in the matrix between the fibres, and in the calcified material some of the granular cells or osteoblasts are enclosed. By the fusion of the calcareous granules the tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The osteoblasts form the bone-cells of the future bone, the spaces in which they are enclosed constituting the lacunæ. As this process advances, a network of bone is formed, the meshes of which contain the blood-vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh layers formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently the bone increases in thickness by the deposition of successive layers under the periosteum and round the larger vascular channels which become the Haversian canals.

Intracartilaginous ossification.—Most of the bones are ossified in cartilage. Each long bone, for example, is represented in early fœtal life by a rod of hyaline cartilage. Ossification commences in the centre of the rod and proceeds towards the ends, which for some time remain cartilaginous. Subsequently ossification begins at one or more centres in either end, and gradually extends, but a superficial layer of cartilage persists, constituting the articular cartilage. The ossified extremities do not, however, fuse with the body of the bone until growth has ceased;

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

between the body and either end a plate of cartilage termed the *epiphysial cartilage* persists throughout the period of growth.

At the *centre of ossification*, or point where the ossifying process begins, the cartilage-cells multiply and enlarge and become arranged in rows radiating from the centre (fig. 36). The matrix in which the cells are imbedded increases in quantity, so that the latter are further separated from each other.

A deposit of calcareous material now takes place in this matrix, so that it presents a granular and opaque appearance. The cartilage-cells are enclosed in oblong cavities, the walls of which are formed of calcified matrix which cuts off all nutrition from the cells; the cells, in consequence, atrophy, leaving spaces called the *primary areolæ*.

While this process is going on in the centre of the bar of cartilage, certain changes are taking place on its surface. This is covered by a very vascular membrane, the *perichondrium*, formed of connective tissue similar to that already described as constituting the basis of membrane-bone; on the inner surface of this—that is to say, on the surface in contact with the cartilage—are gathered the formative cells, the *osteoblasts*. By the agency of these cells a thin layer of bony tissue is laid down, between the perichondrium and the cartilage, by the *intramembranous* mode of ossification just described. There are then, in this first stage, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, bounded by calcified matrix and containing the withered cartilage-cells, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium (now periosteum) (fig. 36, *ir*). The processes consist of blood-vessels and cells—*osteoblasts*, or bone-formers, and *osteoclasts*, or bone-destroyers. The latter are large, multinucleated protoplasmic masses, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (fig. 38). Wherever these processes of the osteogenetic layer come in contact with the calcified walls of the primary areolæ they absorb them, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* or *medullary spaces*. These secondary spaces are filled with embryonic marrow, consisting of osteoblasts and vessels, derived, in the manner described above, from the osteogenetic layer of the periosteum (fig. 37).

FIG. 36.—A section through a fœtal bone of a cat. (From Quain's Elements of Anatomy: Sir Edward Sharpey Schafer.)

im. Subperiosteal bony deposit. *ir.* Irruption of the subperiosteal tissue. *o.* Layer of osteoblasts. *p.* Fibrous layer of the periosteum.

The walls of the secondary areolæ increase in thickness by the deposition of layers of bone on their surface. This process takes place in the following manner. Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as a layer on the surface of the wall of the space (fig. 37). This layer of osteoblasts forms a bony stratum, which gradually covers the wall of the space and in which some of the osteoblasts are included as bone-cells. The next

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

stage in the process consists in the removal of these primary bone-spicules by the osteoclasts, one of which may be seen lying in a Howship's foveola at the free end of each spicule (fig. 38). The removal of the primary spicules goes on *pari passu* with the formation of permanent bone by the periosteum, and in this way the medullary cavity of the bone is formed.

FIG. 37.—A part of a longitudinal section through the developing femur of a human fœtus. Stained with borax carmine. × 100.

This series of changes proceeds gradually towards the ends of the bone, so that all the changes described above may be seen in different parts, from the true bone at the centre of the body to the hyaline cartilage at the extremities.

While the ossification of the cartilaginous body is extending towards the articular ends, the epiphysial cartilage immediately in advance of the osseous tissue continues to grow until the length of the adult bone is reached.

The articular end remains for some time cartilaginous, and then one or more secondary bony centres appear, and initiate in it the process of ossification; but the extremity remains separated from the body of the bone by the epiphysial cartilage for a definite time. This cartilage ultimately ossifies, and the bone assumes its completed form and shape. The same remark applies to such processes of bone as are ossified from separate epiphyses, e.g. the trochanters of the femur. Bones increase in length by ossification continuing to extend into the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by

FIG. 38.—Osteoblasts and osteoclasts in the developing femur of a kitten. × 350.

deposition of new bone, from the deep layer of the periosteum, on their external surfaces, and at the same time an absorption takes place from within, by which the medullary cavities are increased.

The permanent bone formed by the periosteum when first laid down is spongy in structure. Later the osteoblasts contained in its spaces form the concentric layers characteristic of the Haversian systems, and are included as bone-cells.

The number of ossific centres varies in different bones. Most of the short bones are ossified from a single centre. In each long bone there is a primary centre for the body, or diaphysis; and one or more secondary or epiphysial centres for each extremity. That for the body is the first to appear. The times of union of the epiphyses with the body vary inversely with the dates at which their ossifications begin (with the exception of the fibula) and regulate the direction of the nutrient arteries of the bones. Thus, the nutrient arteries of the bones of the arm and forearm are directed towards the elbow, since the epiphyses at this joint become united with the bodies of the bones before those at the opposite extremities. In the lower limb, on the contrary, the nutrient arteries are directed away from the knee; that is, upwards in the femur, downwards in the tibia and fibula; and in them it is observed that the epiphyses at the upper end of the femur, and those at the lower ends of the tibia and fibula, unite first with the bodies. Where there is only one epiphysis, the nutrient artery is directed towards the other end of the bone.

Parsons * groups epiphyses under three headings, viz. (1) *pressure epiphyses*, appearing at the articular ends of the bones and transmitting 'the weight of the body from bone to bone'; (2) *traction epiphyses*, associated with the insertion of muscles, and 'originally sesamoid structures though not necessarily sesamoid bones'; and (3) *atavistic epiphyses*, representing parts of the skeleton which at one time formed separate bones, but which have lost their function 'and only appear as separate ossifications in early life.'

The description here given of the development and growth of bone is in accordance with the generally accepted view. Macewen † has, however, given another account. He asserts that the osteoblasts are produced by division of the nuclei of the cartilage-cells, and that bone-formation is brought about by these cells, the periosteum taking no part in the process. He concludes that the function of the periosteum in the development of bone is mechanical, and is confined to limiting the degree of growth and deciding its direction.

Applied Anatomy.—A knowledge of the arrangements of the nutrient vessels of bones is important in studying injuries and inflammatory conditions to which bones are liable. The free supply of blood to the epiphyses of the long bones is one reason why necrosis does not extend the whole length of the bone. The outer portion of the compact tissue is supplied by periosteal vessels, many of which reach the periosteum through the attachments of the muscles. Where the muscles are well-developed their blood-supply is abundant, and the periosteum is also well supplied with blood, so that the bones are strongly developed and their ridges prominently marked. Conversely, if the muscular development be poor, the bones are thin and light.

When the periosteum becomes separated by extensive injury or inflammatory exudation, the underlying compact tissue, being deprived of its blood-supply, undergoes *necrosis*, i.e. dies, and the dead part is termed a *sequestrum*. In cases of *acute infective periostitis* the inflammatory process affects the whole or a great portion of the diaphysis of a long bone, and the body of the bone dies very rapidly, especially if the single nutrient artery be thrombosed at the same time. The pus which has formed beneath the periosteum is set free by the bursting of the periosteum or by a timely incision; the periosteum then falls back on the necrosed diaphysis and rapidly forms a layer of new bone surrounding the sequestrum. This layer is called the *involucrum*, and the openings in it through which the pus escapes are termed *cloacæ*.

In another type of inflammation of bone the process begins deeply in the growing portion of the epiphysis, and affects mainly the medullary canal, and is known as *osteomyelitis*; very frequently it coexists with acute infective periostitis and the condition is then spoken of as *acute infective necrosis* of bone, or *acute diaphysitis*. When the medullary cavity is filled with pus, septic thrombosis of the veins in the Haversian canals takes place, and there is great danger of septic emboli being displaced and carried into the general circulation, thus setting up a fatal *pyæmia*; in fact pyæmia is more frequently due to septic bone conditions than to any other cause.

The factors involved in the development and growth of bone must be remembered in dealing with the various injuries and diseases that occur during childhood and adolescence. A bone increases in *circumference* by the deposition on its external surface of new bone from the deeper layer of the periosteum, and in *length* by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process.

In *infantile paralysis* where several muscles of a limb become paralysed at a very early period of childhood, the muscles become flaccid and atonic, and their blood-supply is greatly diminished. The periosteal blood-supply suffers and consequently very little

* *Journal of Anatomy and Physiology*, vols. xxxviii., xxxix., and xlii.

† *The growth of bone*, by Sir William Macewen.

Digitized by Arya Samaj Foundation Chennai and eGangotri

fresh osseous tissue is added to the outer surfaces of the bones. In such cases, although the limb continues to grow in length at the epiphysial cartilages, its length is less than that of the normal side, owing to the imperfect nutrition; but the most striking feature about all the long bones of the limb is their extreme thinness.

Since increase in the length of a bone depends on continued growth at the epiphysial cartilages, it is necessary that great care should be taken not to interfere with these in dealing with disease in the neighbourhood of an epiphysis. A knowledge of the periods when the epiphyses join the diaphyses is often of importance in medico-legal enquiries. It is also of practical utility in deciding the nature of an injury in the neighbourhood of a joint, since separation of an epiphysis may simulate a fracture or a dislocation. Further, when amputation through one of the long bones is called for in a young subject the activity of growth at the epiphysial cartilage must be borne in mind. As special cases, amputation through the humerus or tibia may be cited, since in these bones the proximal epiphyses are late in joining the diaphyses. If sufficient allowance be not made for this by cutting long flaps, the portion of the diaphysis remaining will continue to grow till its distal end projects through the stump—a condition known as *conical stump*.

Some of the epiphyses lie entirely within the articular capsules of their corresponding joints, and in such cases disease of the epiphysis is practically synonymous with disease of the joint. The best examples of intra-articular epiphyses are those of the head of the femur and the head of the humerus; the vast majority of cases of tuberculous disease of the hip start as a tuberculous epiphysitis about the intra-articular epiphysial cartilage of the femur; cases of acute septic arthritis of the shoulder- or hip-joints generally have their origins in the intra-articular epiphysial cartilages, and often result in separation of the affected epiphysis. Where an epiphysial cartilage is extra-articular, disease in it does not tend so readily to involve the joint; thus the epiphysial cartilage of the greater trochanter of the femur and that of the upper end of the tibia are outside the joint-capsules, so that if a chronic tuberculous abscess should form in either of these cartilages, its spread into the joint may be prevented by early operation.

Premature arrest of growth of the epiphysial cartilages results in too early junction of the epiphyses with the diaphyses (*premature synostosis*). This brings to an end the growth in length of the bones, and is one of the causes of dwarfism. Persons in whom this has occurred will have the head and trunk of normal size, but the legs and arms disproportionately short though often very strong.

THE CIRCULATING FLUIDS

The **circulating fluids** of the body are the blood and the lymph.

The Blood

The **blood** is an opaque, rather viscid fluid, of a bright red or scarlet colour when it flows from the arteries, of a dark red or purple colour when it flows from the veins. It is salt to the taste, and has a peculiar faint odour and an alkaline reaction. Its specific gravity is about 1·059, and its temperature is generally about 37° C., though varying slightly in different parts of the body.

If a thin film of blood be examined under the microscope it is seen to consist of a faintly yellow fluid, the *plasma* or *liquor sanguinis*, in which are suspended numerous minute particles, the *blood-corpuscles*.

The **blood-corpuscles** are of three kinds: (1) coloured corpuscles or erythrocytes, (2) colourless corpuscles or leucocytes, (3) blood-platelets.

1. The **coloured or red corpuscles** (*erythrocytes*) are circular discs, biconcave in profile. The disc has no nucleus, but, in consequence of its biconcave shape, it presents, when seen on the flat, a central area which, when the more prominent peripheral zone of the corpuscle is in focus, appears dark, and so simulates a nucleus (fig. 39, *a*). The corpuscles vary slightly in size even in the same drop of blood, but the average diameter of each is about 7·5μ, and the thickness about 2μ. Besides these there are certain smaller corpuscles of about one-half of the size just indicated; these are termed *microcytes*, and are very scarce in normal blood; in diseased conditions (e.g. anæmia), however, they are more numerous. It is to the aggregation of the red corpuscles that the blood owes its red hue, although when examined by transmitted light their colour appears to be only a faint reddish yellow. The number of red corpuscles in a cubic millimetre of blood is about 5,000,000 in a man, and 4,500,000 in a woman. Power states that the red corpuscles of an adult would present an aggregate surface of about 3,000 square yards.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

If the mesentery of a living animal be spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the walls of the vessels. But when blood is drawn and examined on a slide, the corpuscles tend to collect into heaps like rouleaux of coins (fig. 39, *c*). During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves, to some extent, to the size of the vessel. They are, however, highly elastic, and speedily regain their form when the pressure is removed. They are readily influenced by the medium in which they are placed. In 0·9 per cent. sodium chloride solution, which is isotonic with human blood-plasma, they are unaltered in shape. In hypotonic solutions they swell up, become globular, and finally rupture, owing to the passage of water from the surrounding medium into the corpuscle (*endosmosis*). In hypertonic solutions, e.g. 2 per cent. sodium chloride, water passes in the reverse direction (*exosmosis*) and the corpuscle shrinks and becomes crenated in appearance (fig. 39, *d*). The surface layer of the erythrocyte thus behaves as a membrane which is permeable to water, but not to salts (semi-permeable membrane), and, for this and other reasons, Sharpey Schafer believes that each corpuscle consists of an envelope containing the coloured substance, hæmoglobin. According to another view, the erythrocyte consists of a stroma or sponge-work permeated by the hæmoglobin. The stroma or envelope consists mainly of cholesterol, lecithin, and nucleoprotein.

FIG. 39.—Human red blood-corpuscles. × 1500.

a. Seen from the surface. *b*. Seen in profile. *c*. Forming rouleaux. *d*. Rendered crenate by salt solution.

The **colourless corpuscles** or *leucocytes* are of various sizes. In human blood the majority are rather larger than the red corpuscles, and measure about 10μ in diameter. On the average from 7,000 to 12,000 leucocytes are found in each cubic millimetre of blood.

FIG. 40.—Varieties of colourless corpuscles found in human blood, stained with Leishman's stain. × 1500.

a. Eosinophil corpuscles. *b*. Polymorphonuclear leucocytes. *c*. Hyaline cell or macrocyte *d*. Lymphocytes.

They consist of minute nucleated masses of protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm, and by the staining reactions of these granules when present (fig. 40). (1) The most numerous and important

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are termed *polymorphonuclear* leucocytes; they are irregular in shape in the living condition, are possessed of the power of amœboid movement, and contain nuclei which often consist of two or three parts (multipartite) connected together by fine threads of chromatin. When at rest or dead, they are spherical in shape as a rule. The protoplasm contains a number of very fine granules, some of which stain with acid dyes, others with neutral dyes, and are therefore called *oxyphil* or *neutrophil* respectively. They constitute 60 to 70 per cent. of the total number of the colourless corpuscles. (2) A second variety comprises from 1 to 4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of coarsely granular protoplasm, the granules being highly refractile and grouped round single nuclei of horseshoe shape. The granules stain deeply with eosin, and the cells are therefore often termed *eosinophil* corpuscles. (3) A third variety is called the *hyaline* cell or *macrocyte*. This is usually about the same size as the eosinophil cell, and, when at rest, is spherical in shape and contains a single round or oval nucleus. The protoplasm is free from granules, but is not quite

Fig. 41.—Human colourless blood-corpuscle, showing its successive changes of outline within ten minutes when kept moist on a warm stage. (Schofield.)

transparent, having the appearance of ground glass. (4) A fourth kind is designated the *lymphocyte*, because it is identical with the cells derived from the lymph-glands, or other lymphoid tissue. They are the smallest of the leucocytes, and each consists of a spheroidal nucleus surrounded by a small quantity of homogeneous protoplasm. The third and fourth varieties together constitute from 20 to 30 per cent. of the colourless corpuscles, but of the two varieties the lymphocytes are by far the more numerous. Leucocytes having in their protoplasm granules which stain with basic dyes (*basiphil*) have been described as occurring in human blood, but they are rarely found except in disease.

The colourless corpuscles are very various in shape in living blood (fig. 41), because many of them have the power of constantly changing their form by protruding finger-shaped or filamentous processes of their substance, by which they move and take up granules from the surrounding medium. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and gradually the rest of the body flows into it. In the same way when any granule or particle comes in its way the corpuscle protrudes a pseudopodium towards it, and then draws the particle into its own substance. By means of these amœboid properties the cells have the power of wandering or emigrating from the blood-capillaries by penetrating between the cells which form their walls and thus finding their way into the extravascular spaces. The solid chemical constituents of leucocytes are nucleo-protein, globulin, fat, cholesterol, lecithin, glycogen, and salts.

Fig. 42.—Blood-platelets. Highly magnified. (After Kopsch.) (From Sharpey Schafer's Essentials of Histology.)

The **blood-platelets** (fig. 42) are discoid or irregularly shaped, colourless, refractile bodies, much smaller than the red corpuscles. Each contains a central chromatin mass resembling a nucleus. Blood-platelets possess the power of amœboid movement. When blood is shed they rapidly disintegrate and form granular masses, setting free *thrombokinase*, a substance which takes part in the production of fibrin and so is concerned in bringing about the coagulation of the blood. It is doubtful whether platelets exist normally in circulating blood.

The development of the blood-corpuscles is described on pp. 109, 110.

The Lymph

The **lymph** is a transparent, colourless or slightly yellow fluid, which is conveyed into the blood by a set of vessels named *lymphatics*. These vessels arise in nearly all parts of the body as *lymph-capillaries*. They take up the fluid which has exuded from the blood-capillaries for the nourishment of the tissues, and return it into the veins. The greater number of these lymphatic vessels empty themselves into the *thoracic duct*, which ascends in front of the vertebral column and opens into the junction of the internal jugular and subclavian veins on the left side of the root of the neck. The remainder empty themselves into a smaller duct which ends in the corresponding veins on the right side of the neck.

Lymph is a watery fluid of sp. gr. about 1·015 ; it closely resembles the blood-plasma, but is more dilute. When it is examined under the microscope, leucocytes of the lymphocyte class are found floating in the transparent fluid ; they are always increased in number after the passage of the lymph through lymphoid tissue, as in lymph-glands.

MUSCULAR TISSUE

Muscular tissue is composed of bundles of reddish fibres endowed with the property of contractility. There are three varieties of muscle, (1) *striped* or *voluntary*, (2) *unstriped* or *involuntary*, and (3) *cardiac*. The muscles which are concerned with the movements of the bony skeleton, the skeletal muscles, are composed of striped fibres, and are under the control of the will. The muscular coats of the stomach and intestines, uterus, bladder and blood-vessels, on the contrary, are formed of unstriped fibres, and their movements are involuntary. Some striped muscles, however, are not under voluntary control, namely, those forming the walls of the pharynx and upper part of the œsophagus. Cardiac muscle is intermediate in position between the other two varieties. Its fibres are striped, but involuntary, and they differ from both striped and unstriped muscle in structure.

Fig. 43.—A transverse section through human striped muscle fibres. × 255.

The **striped muscular fibres** are arranged in bundles or *fasciculi*, in which the individual fibres are parallel to each other. Each fasciculus has a connective tissue sheath, called the *perimysium*, prolongations of which run into the bundle, binding the fibres together and constituting the *endomysium*. A muscle is composed of a number of fasciculi, held together and surrounded by connective tissue which is known as the *epimysium*. The fasciculi are of different sizes in different muscles, and are for the most part placed parallel to each other, though they usually converge towards the tendinous attachments. The connective tissue framework of the muscle contains the blood-vessels and nerves which supply it.

A *muscular fibre* consists of a soft contractile substance, enclosed in a tubular sheath called the *sarcolemma*. The fibres are cylindrical or prismatic in shape (fig. 43), and are of no great length, not exceeding as a rule 40 mm. Their breadth varies in man from 0·01 mm. to 0·1 mm. As a rule, the fibres do not divide or anastomose ; but occasionally, especially in the tongue and facial muscles, they may be seen to divide into several branches. In the substance of the muscle, the fibres end by tapering extremities which are joined to the ends of other fibres by the sarcolemma. Where a muscle joins its tendon, the sarcolemma covering the end of each muscle-fibre blends with a corresponding group of the fine fibres of the tendon. The muscular substance of the fibre can readily be made to retract from the point of junction. The areolar tissue between the fibres is prolonged

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

into the tendon, so as to form a kind of sheath around the tendon-bundles for a longer or shorter distance. When muscular fibres are attached to skin or mucous membranes, this sheath becomes continuous with the areolar tissue of these structures.

Fig. 44.—Striped muscle-fibres from the tongue of a cat. × 250.

The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it sometimes remains entire when the included substance is ruptured. On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in frogs, elongated nuclei are seen, and surrounding each of these is a little granular protoplasm.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be marked by alternate light and dark bands or striæ, which pass transversely across the fibre (fig. 44). When examined by polarised light the dark bands are found to be doubly refracting (anisotropic), while the clear stripes are singly refracting (isotropic). The dark and light bands are of nearly equal breadth, and alternate with great regularity; they vary in breadth from about 1μ to 2μ. When the fibre is deeply focussed a dark line may be seen running in the middle of the clear stripe. This is known as *Dobie's line* or *Krause's membrane*. In fibres which are in the extended condition the dim stripe is often seen to be divided by a clearer line, *Hensen's line*.

Under high magnification there are indications that the striped muscle-fibre is made up of a large number of fibrils, known as *sarcostyles*, together with an interfibrillar material, or *sarcoplasm* (fig. 45, B). When a fibre is treated with weak acid it becomes clearer, and the sarcoplasm is visible as fine, longitudinal, parallel lines. At the junction of the dim and clear stripes these lines often show bead-like enlargements in the extended condition of the fibre. Examination of transverse sections of individual fibres shows that each sarcostyle is surrounded by sarcoplasm, and that the sarcostyles are arranged in groups called *muscle-columns*, the groups being separated by a relatively larger amount of sarcoplasm than the separate fibrils. The sections of muscle-columns, defined in this way, constitute what are known as *Cohnheim's areas*.

Fig. 45.—A. A portion of a medium-sized human muscular fibre. Magnified nearly 800 diameters. B. Separated bundles of fibrils, equally magnified. (From Quain's Elements of Anatomy.)

a, a. Larger, and *b, b,* smaller collections. *c.* Still smaller. *d, d.* The smallest which could be detached.

When the sarcostyles are separated by suitable methods it becomes evident that each exhibits alternate dim and clear portions, with Dobie's and Hensen's lines, and that the striped appearance of the fibre is due to the apposition of the corresponding segments of the fibrils of which it is composed.

Sharpey Schafer has worked out the minute anatomy of muscular fibre, particularly in the wing-muscles of insects, which are peculiarly adapted for this purpose on account of the relatively large size of the sarcostyles and the ease with which they can be separated. In the following description that given by Sharpey Schafer is closely followed.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A sarcostyle may be said to be made up of successive portions, each of which is termed a *sarcomere*. The sarcomere is situated between two membranes of Krause, and consists of (1) a central dark part, which forms a portion of the dark band of the whole fibre, and (2) a clear area at either end, each forming, with the corresponding clear part of the adjacent sarcomere, the light band of the fibril. The central dark segment really consists of two parts, and when the fibre is stretched these two parts become separated from each other at the line of Hensen (fig. 46, A). The clear areas are well marked in the extended sarcostyle, but in the contracted sarcostyle they are small or altogether absent (fig. 46, B).

The central dim portion, or *sarcous element*, does not lie free in the sarcomere, for when the sarcostyle is stretched, very fine lines, which are probably septa, may be seen running through the clear portion from the sarcous element to the membrane of Krause.

Sharpey Schafer explains these phenomena in the following way. He considers that each dim segment contains a number of longitudinal channels, which open into the clear part towards the membrane of Krause but are closed at the line of Hensen. When the muscular fibre contracts the clear part of the muscular substance passes into these channels or tubes, and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere.

FIG. 46.—A diagram of a sarcomere. (After Sharpey Schafer.)

A. In a moderately extended condition. B. In a contracted condition.

H. Line of Hensen. *k*, *k*. Membranes of Krause. S.E. Sarcous element.

When, on the contrary, the fibre is extended, this clear substance is driven out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

Sharpey Schafer has shown that, if this view be correct, it harmonises the contraction of muscle with the amœboid action of protoplasm. In an amœboid cell there is, according to one view of the structure of protoplasm, a framework of spongioplasm, enclosing in its meshes a clear substance, hyaloplasm. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out, as in the formation of pseudopodia. In muscle there is the same thing, viz. a framework of spongioplasm—the substance of the dim segment; and this encloses a clear hyaloplasm, the clear substance of the sarcomere. During contraction of the muscle—i.e. under stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—i.e. when there is no stimulation—it tends to pass out of the spongioplasm. In this way the contraction is brought about; under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

Vessels and nerves of striped muscle.—The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. In the red muscles of the rabbit dilatations occur on the transverse branches of the capillary network. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi. *Nerves* are profusely distributed to striped muscle. Their mode of termination is described in the chapter on Neurology. *Lymphatic vessels* do not occur in striped muscle, though they have been found in tendons and in the sheaths of the muscles.

The **unstriped, plain,** or **involuntary muscle** is found in the following situations—in the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi; in the gall-bladder and common bile-duct; in the large ducts of the salivary and pancreatic glands; in the pelvis and calyces of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz. the ovary, the uterine tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the corpora cavernosa of the clitoris; in the male sexual organs—viz. the Dartos of the scrotum, the ductus deferentes and epididymes, the vesiculæ seminales, the prostate, and the corpora cavernosa of the penis and urethra; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the Arrectores pilorum, and also in the sweat-glands; in the mammary glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

A. Complete cell. B. Broken cell showing delicate external layer.

Fig. 48.—Anastomosing muscular fibres of the heart seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically. (Schweigger-Seidel.)

Unstriped or plain muscle is made up of spindle-shaped cells (fig. 47), collected into bundles and held together by a cement-substance. These bundles are further aggregated into larger fasciculi, or sheets, bound together by ordinary connective tissue.

The cells are elongated, spindle-shaped, and nucleated, and are of various sizes, averaging from 40μ to 80μ in length, and 6μ to 7μ in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure. Each presents a faint longitudinal striation and consists of an elastic cell-wall containing the contractile substance, and an oval or rod-like nucleus. A centriole lies close to the nucleus. The fibres are attached to one another by a certain amount of interstitial cement-substance which reduces nitrate of silver, but in some regions, e.g. the muscular coats of the intestines, the muscle-cells are also connected by 'bridges' similar to those which occur in the prickle-cells of the epidermis.

Sheets of smooth muscle frequently exhibit rhythmical contractions, which are more sluggish than the contractions of striped muscle, and in many cases travel

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

along the membrane in the form of waves. Such waves are well marked in the wall of the intestine. Contraction is often excited by a mechanical stimulus, as distension, for example, in the urinary bladder.

The **cardiac muscular tissue.**—The fibres of the heart differ very remarkably from those of other striped muscles. They are striated both transversely and longitudinally, but the striation, as compared with that of striped muscle, is faint and indistinct. The fibres are made up of quadrangular cells joined end to end so as to form a syncytium (fig. 48). Each cell contains a clear oval nucleus, situated near its centre. Many of the cells branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

Purkinje's fibres (fig. 49).—Between the endocardium and the ordinary cardiac muscle are found, embedded in a small amount of connective tissue, peculiar fibres known as *Purkinje's fibres.* They are associated with the terminal distributions of the atrioventricular bundle. The fibres are very much larger in size than the cardiac cells and differ from them in several ways. In longitudinal section they are quadrilateral in shape, being about twice as long as they are broad. The central portion of each fibre contains one or more nuclei and is made up of granular protoplasm, with no indication of striation, while the peripheral portion is fibrillated and has transverse striations. The fibres are intimately connected with each other, possess no definite sarcolemma, and do not branch. They form a considerable portion of the moderator band in the heart of the sheep.

FIG. 49.—Purkinje's fibres from the sheep's heart. × 250.

A. In longitudinal section.
B. In transverse section.

The **atrioventricular bundle** (see chapter on Angiology) is composed of cells which differ from ordinary cardiac muscle-cells in being more spindle-shaped. They are, moreover, more loosely arranged and have a richer vascular supply than the rest of the cardiac muscle.

Development of muscle-fibres.—Voluntary muscular fibres are developed from the mesoderm, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibre, spreads around the circumference, and ultimately extends to the centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of involuntary muscle the mesodermal cell assumes a pointed shape at the extremities and becomes flattened, the nucleus also lengthening out to its permanent rod-like form.

NERVOUS TISSUE

The **nervous tissues** of the body comprise the brain, the medulla spinalis or spinal cord, the cerebral, spinal, and sympathetic nerves, and the ganglia connected with them.

The nervous tissues are composed of *nerve-cells* and their various processes, together with a supporting tissue called *neuroglia*, which, however, is found only in the brain and medulla spinalis. Certain long processes of the nerve-cells are of special importance, and it is convenient to consider them apart from the cells; they are known as *nerve-fibres.*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

To the naked eye a difference is obvious between certain portions of the brain and medulla spinalis, viz. the *grey* substance, and the *white* substance. The grey substance is largely composed of nerve-cells, while the white substance contains only their long processes, the nerve-fibres. It is in the former that nervous impressions are received, stored, and transformed into efferent impulses, and by the latter that they are conducted. Hence the grey substance forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the brain and medulla spinalis; while the white substance forms the bulk of the commissural portions of the nerve-centres and the peripheral nerves.

Neuroglia, the peculiar variety of connective tissue which binds together the true nervous constituents of the brain and medulla spinalis, consists of cells and fibres. Some of the cells (spider-cells) are stellate in shape, with ill-defined cell-bodies and their fine processes become neuroglia fibres, which extend radially and unbranched (fig. 50, B) among the nerve-cells and fibres which they aid in supporting.

FIG. 50.—Neuroglia-cells of the brain shown by Golgi's method. (After Andriezen.) (From Sharpey Schafer's Essentials of Histology.)

A. Arborescent cell with branched processes. B. Spider-cell with unbranched processes.

Other cells (arborescent cells) give off processes which branch repeatedly (fig. 50, A). Some of the fibres start from the epithelial cells lining the ventricles of the brain and central canal of the medulla spinalis, and pass through the nervous tissue branching repeatedly, to end in slight enlargements on the pia mater. Thus neuroglia is evidently a connective tissue in function, but it is not so in development; it is ectodermal in origin, whereas all other connective tissues are mesodermal.

Nerve-cells (fig. 51) are largely aggregated in the grey substance of the brain and medulla spinalis, but smaller collections of these cells also form the swellings, called *ganglia*, seen on many nerves. These latter are found chiefly upon the spinal and cerebral nerve-roots and in connexion with the sympathetic nerves.

Nerve-cells vary in shape and size, and have one or more processes. They may be divided for purposes of description into three groups according to the number of processes which they possess. (1) Unipolar cells are found in the spinal ganglia; the single process, after a short course, divides in a T-shaped manner (fig. 51). These cells are bipolar in embryonic life, but, as development proceeds the two processes approach one another and become fused for a short distance. In the spinal ganglia of fish the cells are bipolar throughout life. (2) Bipolar cells (fig. 51) are found, in the adult, in the retina, and in the ganglion spirale and ganglion vestibulare of the acoustic nerve. In some cases where two fibres are

CC-0.In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

apparently connected with a cell, one of the fibres is really derived from an adjoining nerve-cell and is passing to end in a ramification around a unipolar cell, or, again, it may be coiled spirally round the nerve-process which is issuing from the cell. (3) Multipolar cells are pyramidal or stellate in shape, and characterised by the

FIG. 51.—Various forms of nerve-cells.

numerous processes which issue from them. The processes are of two kinds: one of them is termed the *axis-cylinder process* or *axon* because it becomes the axis-cylinder of a nerve-fibre (figs. 52, 53, 54). The others are termed the *protoplasmic processes* or *dendrons*; they begin to divide and subdivide as soon as they emerge from the cell, and finally end in minute twigs. The axons of certain multipolar

FIG. 52.—A motor nerve-cell from the anterior horn of the medulla spinalis of an ox, stained with methylene blue. ×500. The spindle-shaped Nissl's granules are shown. The dendrons and axon are broken off close to the cell.

cells terminate by arborescence close to the cell-bodies; such cells were called by Golgi multipolar cells of the second type.

The body of the nerve-cell is known as the *cyton*. In fixed and stained preparations it consists of a finely fibrillated protoplasmic material in which there are occasionally patches of a deeper tint, caused by the aggregation of pigment-granules at the sides of the nuclei, as in the substantia nigra and locus cæruleus of the brain.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The protoplasm also contains peculiar angular masses of granules, which stain deeply with basic dyes such as methylene blue; these are known as *Nissl's spindles* (fig. 52). They extend into the dendritic processes but not into the axis-cylinder; the small clear area at the point of exit of the axon is termed the *cone of origin*. These bodies disappear (*chromatolysis*) during fatigue or after section of the nerve fibre connected with the cell. They are supposed to represent a store of nervous

FIG. 53.—A pyramidal cell from the cerebral cortex of a mouse. Golgi method. (After Ramón y Cajal.)

FIG. 54.—A cell of Purkinje from the cerebellum. Golgi method. (Ramón y Cajal.)

energy, and in various mental diseases are deficient or absent. The nucleus is, as a rule, a large, well-defined body, with a relatively small amount of chromatin, and contains a well-marked nucleolus.

In addition to the protoplasmic network described above, each nerve-cell may be shown to have delicate neurofibrils running through its substance (fig. 55); these fibrils are continuous with the fibrils of the axon, and are believed to convey nerve impulses. A *pericellular network* of fine branching fibres is a characteristic feature of many nerve-cells.

Mott and Marinesco have shown that, when living nerve-cells are examined by the dark ground illumination method, neither Nissl's bodies nor fibrils of any kind can be seen. The constancy of the occurrence of both these structures in fixed

CC-0. Panini Kanya Maha Vidyalaya Collection. Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

preparations, however, indicates that they represent something specific in the living cell.

Nerve-fibres are found universally in the peripheral nerves, and in the white substance of the brain and medulla spinalis. They are of two kinds—viz. *medullated* or *white* fibres, and *non-medullated* or *grey* fibres.

The *medullated fibres* form the white part of the brain and medulla spinalis, and also the greater part of every cerebral and spinal nerve, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body each fibre presents, when examined by transmitted light, a double outline or contour, as if consisting of two parts (fig. 56). The central portion is named the *axis-cylinder*; around this is a sheath of fatty

Fig. 55.—Nerve-cells of a kitten, showing neurofibrils. (Ramón y Cajal.)

a. Axon. *b*. Cyton. *c*. Nucleus. *d*. Neurofibrils.

material, staining black with osmic acid, named the *white substance of Schwann* or *medullary sheath*, which gives to the fibre its double contour; and the whole is enclosed in a delicate membrane, the *neurolemma*, *primitive sheath*, or *nucleated sheath of Schwann* (fig. 57). Medullated nerve-fibres vary in diameter from 2μ to 16μ.

The *axis-cylinder* is the essential part of the nerve-fibre, and is always present; the medullary sheath and the neurolemma are occasionally absent, especially at the origin and termination of the nerve-fibre. The axis-cylinder undergoes no interruption from its origin in the nerve-centre to its termination, and must be regarded as a direct prolongation of a nerve-cell. Nerve-fibres in the white substance of the brain and medulla spinalis give off twigs known as *collaterals*. These arise from the main fibre at right angles to its course and run into the grey substance, where they terminate by arborisation. The axis-cylinder constitutes about one-half or one-third of the nerve-fibre, being greater in proportion in the fibres of the central organs than in those of the nerves. It is quite transparent, and is therefore

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils (figs. 57 and 58), which stain darkly with gold chloride and at its termination may be seen to break up into these fibrils. The axis-cylinder is said by some to be enveloped in a special reticular sheath, which separates it from the medullary sheath, and is composed of a substance called *neurokeratin*. The more common opinion is that this network or reticulum is contained in the white substance of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it.

FIG. 56.—Medullated nerve-fibres. × 350.

The *medullary sheath* or *white substance of Schwann* (fig. 57) is regarded as being a fatty material in a fluid state, which insulates and protects, or possibly supplies nutriment to, the essential part of the nerve—the axis-cylinder. As a general rule its thickness is proportional to the size of the axis-cylinder, and is such that it forms about half of the total area of the cross section of the fibre. Its continuity is interrupted at intervals of about 1 mm., giving to the fibre the appearance of constriction at these points; these are known as the *nodes of Ranvier* (figs. 56 and 57). The portion of nerve-fibre between two nodes is called an *internodal segment*. The neurolemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. Some

FIG. 57.—A diagram of longitudinal sections of medullated nerve-fibres. Osmic acid.

observers, however, believe that the neurolemma of one internodal segment is connected with that of the adjacent segment at the node by cement-substance. If the fibre be treated with silver nitrate the reagent penetrates the neurolemma at the nodes, and, on exposure to light, reduction takes place, giving rise to the appearance of black crosses, *Ranvier's crosses*, on the axis-cylinder. There may also be seen transverse lines beyond the nodes termed *Frommann's lines* (fig. 59); the significance of these is not understood. In addition to these interruptions, oblique clefts or *incisures* may be seen in the medullary sheath, subdividing it into irregular portions, which are termed *medullary segments*, or *segments of Lantermann* (figs. 56 and 57); there is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined in the fresh condition, frequently present a beaded or varicose appearance, due to

FIG. 58.—Transverse sections through medullated nerve-fibres. Osmic acid.

Digitized by Arya Samaj Foundation Chennai and eGangotri

manipulation and pressure causing the oily matter to collect into drops; in consequence of the extreme delicacy of the primitive sheath even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the sheath.

The *neurolemma* or *primitive sheath* is a delicate, structureless membrane; here and there beneath it, and situated in depressions in the white substance of Schwann, are nuclei, each surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and one is generally found in the middle of each internode. The primitive sheath is absent from the medullated fibres of the brain and medulla spinalis.

FIG. 59.—Medullated nerve-fibres stained with silver nitrate.

FIG. 60.—A small branch from the sympathetic trunk of a mammal.

a. Two small medullated nerve-fibres among a number of non-medullated nerve-fibres, *b.*

Wallerian Degeneration.—When nerve-fibres are cut across, the central ends of the fibres degenerate as far as the first node of Ranvier; but the peripheral ends degenerate simultaneously throughout their whole length. The medullary sheath of each fibre becomes broken down, forming droplets of fatty substance, and the axon undergoes fragmentation. The nuclei of the primitive sheath proliferate, and finally absorption of the axons and fatty substance occurs. If the cut ends of the nerve be sutured together, regeneration of the nerve-fibres takes place by the downgrowth of axons from the central end of the nerve. At one time it was believed that the regeneration was peripheral in origin, but this has been disproved, the proliferated nuclei in the peripheral portions taking part merely in the formation of the so-called scaffolding along which the new axons pass.

Non-medullated fibres.—Most of the fibres of the sympathetic system, and some of the cerebrospinal, consist of the *grey* or *gelatinous* nerve-fibres—*fibres of Remak* (fig. 60). Each of these consists of an axis-cylinder to which nuclei are applied at intervals. These nuclei are believed to be in connexion with a delicate sheath corresponding with the neurolemma of the medullated nerve-fibre. In external appearance the non-medullated nerve-fibres are semitransparent and grey or yellowish-grey. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

EMBRYOLOGY

THE term **Embryology,** in its widest sense, comprises the various changes which take place during the growth of an animal from the egg to the adult condition; it is, however, usually restricted to the phenomena which occur before birth.

In vertebrate animals the development of a new being normally takes place when a female germ-cell or *ovum* has been fertilised by a male germ-cell or *spermatozoön*. The ovum is a nucleated cell, and the complicated changes by which the various tissues and organs of the body are formed from it, after it has been fertilised, are the result of two general processes, viz. *segmentation* and *differentiation* of cells. Thus, the fertilised ovum undergoes repeated segmentation into a number of cells which at first closely resemble one another, but are, sooner or later, differentiated into two groups: (1) *somatic cells*, the function of which is to build up the various tissues of the body; and (2) *germinal cells*, which are ultimately imbedded in the genital glands (ovaries and testes), and destined for the perpetuation of the species.

Having regard to the main purpose of this work, it is impossible, in the space available in this chapter, to describe or illustrate fully, all the changes which occur during the development of the human body. Only the principal facts are given, and the student is referred for further details to one or other of the text-books * on embryology.

THE OVUM

The ova are derived from the primitive germ-cells which are situated in the substance of the ovaries; each primitive germ-cell gives rise, by repeated divisions, to a number of smaller cells termed *oögonia* from which the *ova* or *primary oöcytes* are developed.

Human ova measure about 0·1 mm. in diameter, and are contained within the Graafian follicles of the ovaries †; as a rule each follicle contains one ovum, but sometimes two or more are present. By the enlargement and subsequent rupture of a follicle at the surface of the ovary, an ovum is liberated and enters the uterine tube through which it is conveyed to the cavity of the uterus. Unless it be fertilised it is discharged from the uterus, but if fertilisation takes place it is retained there and developed into a new being.

In appearance and structure the ovum (fig. 61) differs little from an ordinary cell (p. 1), but distinctive names are given to its several parts; thus, the cell-substance is known as the *yolk* or *oöplasm*, the nucleus as the *germinal vesicle*, and the nucleolus as the *germinal spot*. The ovum has a thick, transparent envelope named the *zona striata* or *zona pellucida*, and when the ovum is liberated from the Graafian follicle, several layers of cells, derived from those of the follicle, adhere to the outer surface of the zona striata, and collectively constitute the *corona radiata*.

The **yolk** comprises (1) *cytoplasm* similar to that of the ordinary animal cell (p. 1), and frequently termed the *formative yolk*; (2) *deuteroplasm* or *nutritive yolk*, which consists of numerous round granules of fatty and albuminoid substances imbedded in the cytoplasm. In the mammalian ovum the deuteroplasm is extremely small in amount, and nourishes the embryo in the early stages of its

development only, whereas in the egg of the bird there is sufficient to supply the chick with nutriment throughout the whole period of incubation. The mode of distribution of the deuteroplasm within the egg varies in different animals; in some it is almost uniformly dispersed throughout the cytoplasm; in some it is centrally placed and surrounded by the cytoplasm; in others it is accumulated at the lower pole of the ovum, while the cytoplasm occupies the upper pole. A *centrosome* and *centriole* are present and lie in the immediate neighbourhood of the nucleus.

FIG. 61.—A human ovum examined fresh in the liquor folliculi. ×500. (Waldeyer.)

The zona pellucida is seen as a thick clear girdle surrounded by the cells of the corona radiata. The ovum shows a central granular deuteroplasmic area and a peripheral clear cytoplasmic layer, and encloses the germinal vesicle, in which the germinal spot is indistinctly seen.

The **nucleus** or **germinal vesicle** is a large spherical body which usually occupies an excentric position in the yolk. Its structure is that of an ordinary cell-nucleus, viz. it consists of a reticulum or karyomitome the meshes of which are filled with karyoplasm, while connected with, or imbedded in, the reticulum are a number of chromatin masses or chromosomes, which may present the appearance of a skein or may assume the form of rods or loops. The nucleus is enclosed by a delicate nuclear membrane, and contains in its interior a well-defined nucleolus or germinal spot.

THE COVERINGS OF THE OVUM

The **zona striata** or **zona pellucida** (fig. 61) is a thick membrane, which, under the higher powers of the microscope, is seen to be radially striated. Thomson* describes the zona pellucida as consisting of (*a*) an inner, homogeneous layer which

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

* Professor Arthur Thomson, *Journal of Anatomy*, vol. liii. 1919.

Digitized by Arya Samaj Foundation Chennai and eGangotri

is derived from the ovum, and (*b*) an outer, fibrillar layer formed by the felting of the basal fibres of the innermost cells of the corona radiata. He is also of opinion that there is distinct evidence of a *vitelline membrane* within the zona pellucida.

The **corona radiata** (fig. 61) consists of two or three strata of cells which are derived from the cells of the Graafian follicle, and adhere to the outer surface of the zona striata when the ovum is set free from the follicle; the cells are radially arranged around the zona, those of the innermost layer being columnar in shape. The cells of the corona radiata soon disappear; in some animals they secrete, or are replaced by, a layer of protein, which may assist in protecting and nourishing the ovum.

The phenomena attending the discharge of the ova from the Graafian follicle are described with the anatomy of the ovaries.

THE MATURATION OF THE OVUM

Before an ovum or primary oöcyte can be fertilised it must undergo a process of *maturation* or *ripening* (fig. 62). This process consists of a heterotypical division of the ovum into two cells, followed by a homotypical division of the two cells into four. Three of the four cells are small, incapable of further development,

FIG. 62.—The formation of the polar bodies in Asterias glacialis. (Slightly modified from Hertwig.)

In fig. I the polar spindle (*sp*) has advanced to the surface of the egg. In fig. II a small elevation (pb^1) is formed which receives half of the spindle. In fig. III the elevation is constricted off, forming the first polar body (pb^1), and a second spindle is formed. In fig. IV is seen a second elevation which in fig. V has been constricted off as the second polar body (pb^2). Out of the remainder of the spindle (*f.pn* in fig. VI) the female pronucleus is developed.

and are named *polar bodies* or *polocytes*. The fourth cell is large; it is named the *mature ovum*, and is devoid of a centrosome. Its nucleus, as the result of the heterotypical division, contains only one-half of the number of chromosomes present in the nucleus of the primary oöcyte. The nucleus of the mature ovum is named the *female pronucleus*.

In most vertebrates the heterotypical division occurs before the ovum or primary oöcyte is liberated from the ovarian or Graafian follicle, and the homotypical division after a spermatozoön has penetrated the zona pellucida. Thomson * has submitted evidence to show that in man both polar bodies are extruded before the ovum is liberated from the Graafian follicle; in other words, the process of maturation is completed before the ovum has been subjected to the influence of a spermatozoon.

The process of maturation of the ovum has been carefully studied in the ova of some of the lower animals, to which the following description applies.

It was pointed out on page 2 that the number of chromosomes found in the nucleus is constant for all the cells in an animal of any given species, and that

* *Loc. cit.*

Digitized by Arya Samaj Foundation Chennai and eGangotri

man the number is probably twenty-four.* This applies not only to the somatic cells but to the primitive ova and their descendants. For the purpose of illustrating the process of maturation a species may be taken in which the number of nuclear chromosomes is four (fig. 63). If an ovum from such be observed at the beginning of the maturation process, the usual achromatic spindle is seen lying close to and parallel with the surface of the ovum, with the four chromosomes arranged at its

FIG. 63.—A diagram showing the reduction in number of the chromosomes during the maturation of the ovum. The first division is heterotypical, the second homotypical.

equator. The spindle then rotates so that its long axis is radial, and the first or heterotypical division takes place; two chromosomes pass to either end of the spindle, those at the periphery producing a surface elevation which is constricted off as the *first polar body*. The other two chromosomes are retained in the ovum, which is now termed a *secondary oöcyte*. Without passing through a resting stage the secondary oöcyte undergoes homotypical division, the two chromosomes each dividing into two, which travel to the ends of the spindle. A *second polar body* is segmented off, and the *mature ovum*, with two chromosomes gathered into a newly formed nucleus, remains. The first polar body frequently divides in a homotypical manner while the second is being formed, and as a final result four cells are produced, viz. the mature ovum and three polar bodies, each of which contains two chromosomes, i.e. one-half of the number present in the nuclei of the somatic cells of members of the same species.

THE SPERMATOZOÖN

The spermatozoa or male germ-cells are developed in the testes and are present in enormous numbers in the seminal fluid. Each consists of a small but greatly modified cell, and possesses a head, a neck, a connecting piece or body, and a tail (fig. 64).

The **head** is ovoid or elliptical, but flattened, so that when viewed in profile it is pear-shaped. Its anterior two-thirds are covered with a layer of modified protoplasm, named the *head-cap*, which ends anteriorly in a sharp edge. In some animals (e.g. the salamander), the head-cap is prolonged into a barbed spear-like process (*acrosome* or *perforator*), which probably facilitates the entrance of the spermatozoön into the ovum.

* H. von Winiwarter maintains that the number of chromosomes in the immature ovum is forty-eight, and in the primary spermatocyte, forty-seven.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **neck** is less constricted in the human spermatozoön than in the spermatozoa of some of the lower animals. The *anterior centriole* is situated at the junction of the head and neck, and behind it is a band of homogeneous substance.

The **connecting piece** or **body** is rod-like, and is limited behind by a *terminal disc* or *ring*. The *posterior centriole* is placed at the junction of the body and neck and from it an *axial filament*, surrounded by a sheath, runs backwards through the body and tail. In the body the sheath of the axial filament is encircled by a *spiral thread*, around which is an envelope containing chondriosomes or mitochondrial granules, and termed the *mitochondrial sheath*.

The **tail** consists of the axial thread or filament, surrounded by a thin protoplasmic sheath ; the terminal portion or *end-piece* of the tail is composed of the axial filament only.

Krause gives the length of the human spermatozoön as between 52μ and 62μ, the head measuring 4μ to 5μ, the connecting piece 6μ, and the tail from 41μ to 52μ.

FIG. 64.—A human spermatozoa, highly magnified. A. Profile view. B. Surface view. (After Retzius.) C. A diagrammatic representation of the head, neck and connecting piece, more highly magnified. (Modified from Meves.)

By virtue of their tails, which act as propellers, the spermatozoa are capable of free movement, and if placed in favourable surroundings (e.g. in the female passages) will retain their vitality and fertilising power for several days. In certain animals (e.g. bats) it has been proved that spermatozoa which have been retained in the female passages for several months are capable of fertilising ova.

The spermatozoa are developed from the primary germ-cells imbedded in the testes, and the stages of their development are very similar to those of the maturation of the ovum. The primary germ-cells undergo division and produce a number of cells termed *spermatogonia*, and from these the *primary spermatocytes* are derived. Each primary spermatocyte divides heterotypically into two *secondary spermatocytes*, in the nuclei of which the number of chromosomes is reduced by one-half and each secondary spermatocyte divides homotypically into two *spermatids* or young spermatozoa ; each primary spermatocyte therefore gives rise to four spermatozoa.

Interesting changes occur during the conversion of the spermatid into the spermatozoön (fig. 65). The two centrioles are at first tangential to the surface of the spermatid but soon assume a radial position so that one lies deeper than the other; the deeper one forms the anterior centriole of the neck. The axial

FIG. 65.—The transformation of a spermatid into a spermatozoön. Diagrammatic. (Modified from Meves.)

filament grows out from the superficial centriole, which divides into two parts; the anterior part forms the posterior centriole of the neck, and the posterior part, which is ring-like, migrates to the distal end of the connecting piece or body and there forms the terminal disc or ring, through which the axial filament passes.

FIG. 66.—A scheme showing the analogies in the process of maturation of the ovum and the development of the spermatids (young spermatozoa).

The nucleus of the spermatid forms the head of the spermatozoön, and the cytoplasm, the investing sheath of the body and tail. The centrosome probably moves away from the centrioles to the opposite side of the nucleus and is converted into the head-cap.

On comparing the development of the spermatozoön with the maturation of th ovum (fig. 66) it will be observed that the primary spermatocyte gives rise to tw secondary spermatocytes, and the primary oöcyte to the secondary oöcyte and th first polar body; the two secondary spermatocytes give origin to four spermatozo and the secondary oöcyte and first polar body to four cells, the mature ovum an three polar bodies. In the development of the spermatozoön, as in the maturatio of the ovum, there is a reduction of the nuclear chromosomes to one-half of tho present in the primary spermatocyte. But here the similarity ends, for it mu be noted that the four spermatozoa are of equal size, and each is capable of fertilisin a mature ovum, whereas the three polar bodies are much smaller than the matu ovum, incapable of further development, and may be regarded as abortive ova.

THE FERTILISATION OF THE OVUM

Fertilisation consists in the union of the spermatozoön with the mature ovu (fig. 67). Nothing is known regarding the fertilisation of the human ovum, but th various stages of the process have been studied in other mammals, and from th knowledge so obtained it is believed that fertilisation of the human ovum take

FIG. 67.—The process of fertilisation in the ovum of a mouse. (After Sobotta.)

place in the lateral or ampullary part of the uterine tube. The fertilised ovum i then conveyed along the tube to the cavity of the uterus—a journey occupyin about seven or eight days; during the journey the ovum loses its corona radiat and zona striata, and undergoes segmentation. Having pierced the yolk, th spermatozoön loses its tail, while its head and connecting piece assume the form of a nucleus containing a cluster of chromosomes. This constitutes the *male pro nucleus*, and associated with it there are a centrosome and centriole. The mal pronucleus passes more deeply into the yolk, and the granules of the cytoplasm

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

surrounding it become radially arranged. The male and female pronuclei migrate towards each other, and, meeting near the centre of the yolk, fuse to form the *first segmentation nucleus* which thus contains both male and female chromatin; the former probably transmits the individualities of the paternal, the latter those of the maternal, ancestors to the future embryo. By the union of the male and female pronuclei the number of chromosomes is restored to that present in the nuclei of the somatic cells.

Applied Anatomy.—Sometimes the fertilised ovum is arrested in the uterine tube, and there undergoes development, giving rise to a *tubal pregnancy*; or it may fall into the abdominal cavity and produce an *abdominal pregnancy*. Occasionally the ovum is not expelled from the Graafian follicle when the latter ruptures, but is fertilised within the follicle and produces what is known as an *ovarian pregnancy*. Under normal conditions only one spermatozoön enters the yolk and takes part in the process of fertilisation. Occasionally a second spermatozoön may enter the yolk, thus giving rise to a condition of *polyspermy*; when this occurs the ovum usually develops in an abnormal manner and gives rise to a monstrosity.

z.p. Zona striata. *p.gl.* Polar bodies. *a.* Two-cell stage. *b.* Four-cell stage. *c.* Eight-cell stage. *d, e.* Morula stage.

The **role of the chromosomes.***—According to recent researches the mature ovum contains within itself all the essentials for the formation of a new being, and in the lower forms is capable of producing such when stimulated by mechanical or chemical means. It is interesting to note that the sex of an animal so formed is male. The development of a female necessitates the presence of a spermatozoön containing an additional or specialised chromosome. Thus in some insects the primary oöcyte contains twenty-four chromosomes, and the primary spermatocyte, twenty-three. The mature ovum and the polar bodies each contain twelve chromosomes, while one-half of the spermatozoa contain twelve, and the other half, eleven. If a mature ovum be fertilised by a spermatozoön with eleven chromosomes, the resulting embryo is a male, but if it be fertilised by a spermatozoön with twelve chromosomes, a female embryo is produced. This, however, is not the only factor involved in the determination of sex. The theory advanced is that the chromosomes contain materials which chemically initiate and control the processes that lead to the development of the various tissues and their individual peculiarities. The establishment of a sex-difference is therefore, in the first instance, dependent on a specialised chromosome, but the development of the sexual features results from the presence of specialised chemical substances.

THE SEGMENTATION OF THE FERTILISED OVUM

The early segmentation of the human ovum has not yet been seen, but from what is known to occur in other mammals it may be regarded as certain that the process starts immediately after fertilisation, i.e. while the ovum is in the uterine tube. The nucleus exhibits the usual mitotic changes, and these are succeeded by division of the fertilised ovum into two cells of nearly equal size.* The process

FIG. 69.—A section through the blastodermic vesicle of Vespertilio murinus. (After van Beneden.)

FIG. 70.—A section through the embryonic disc of Vespertilio murinus. (After van Beneden.)

FIG. 71.—A section through the embryonic disc of Vespertilio murinus to show the formation of the amniotic cavity. (After van Beneden.)

* In the mammalian ovum the deuteroplasm is small in amount and uniformly distributed throughout the cytoplasm; such an ovum undergoes *complete* division during the process of segmentation, and is therefore termed *holoblastic*. In the ova of birds, reptiles, and fishes, where the nutritive yolk forms by far the larger portion of the egg, the cleavage is limited to the formative yolk, and is therefore only *partial*; such ova are termed *meroblastic*. Again, it has been observed, in some of the lower animals, that the pronuclei do not fuse but merely lie in apposition. At the commencement of the segmentation process the chromosomes of the two pronuclei group themselves around the equator of the nuclear spindle and then divide; an equal number of male and female chromosomes travel to the opposite poles of the spindle, and thus the male and female pronuclei subscribe equal shares of chromatin to the nuclei of the two cells which result from the subdivision of the fertilised ovum.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is repeated again and again, so that the two cells are succeeded by four, eight, sixteen, thirty-two, and so on, with the result that a mass of cells is found within the zona striata, and to this mass the term *morula* is applied (fig. 68). The cells of the morula, at first closely aggregated, soon arrange themselves into (1) an outer or peripheral layer, the *trophoblast*, which takes no part in the formation of the embryo proper but is concerned in the formation of a protecting membrane, the chorion, from part of which a portion of the placenta is subsequently developed, and (2) an *inner cell-mass*, from a portion of which the embryo is developed. In most mammals fluid collects between the trophoblast and the greater part of the inner cell-mass, and thus the morula is converted into a vesicle which encloses the *segmentation cavity* (fig. 69). The inner cell-mass remains in contact, however, with the trophoblast at one pole of the ovum; this is named the *embryonic pole*, since it indicates the situation where the future embryo is developed. In the human ovum (figs. 72 to 74) there is no actual segmentation cavity but the inner and outer cell-masses are separated in part by delicate strands of mesoderm (magma réticulé or primitive mesoderm). Clefts appear in the magma réticulé, on either side of the developing inner cell-mass, and run together to form the *extra-embryonic cœlom* (fig. 74).

FIG. 72.—A diagram showing the first differentiation of the inner cell-mass.

FIG. 73.—A diagram showing the early stages in the formation of the amnion and archenteron.

FIG. 74.—A diagram showing the commencing formation of the extra-embryonic cœlom.

The trophoblast differentiates into two strata: an outer, the *syncytium* or *syncytiotrophoblast*, consisting of a layer of protoplasm studded with nuclei, but showing no evidence of subdivision into cells; and an inner, the *cytotrophoblast* or *layer of Langhans*, in which the cell-outlines are defined. As already stated, the trophoblast takes no share in the formation of the embryo proper; it forms the ectoderm of the chorion and plays an important part in the imbedding of the ovum in the uterine mucous membrane, and in the development of the placenta. The inner cell-mass divides into a dorsal, ectodermal, and a ventral, entodermal, part. Spaces appear between the cells of both parts and coalesce to form cavities; the cavity in the ectodermal part is named the *amniotic cavity*, that in the entodermal part, the *archenteron* (figs. 72, 73). The floor of the amniotic cavity is formed by the *embryonic disc* composed of a layer of prismatic cells, the *embryonic ectoderm*, which is in apposition with the *entoderm* of the archenteron (fig, 71).

The **formation of the mesoderm—the primitive streak.**—The development of the mesoderm has not been observed in the human ovum, seeing that it is already present in the youngest human ova that have been examined. From what has

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

been observed in other animals it may be concluded that the primitive streak is its principal source. The embryonic disc becomes oval and then pear-shaped. Near its narrow, caudal end an opaque streak, the *primitive streak* (fig. 75), makes its appearance and extends along the middle of the disc for a considerable part of its length; at the cephalic end of the streak there is a knob-like thickening of the ectoderm termed *Hensen's knot*. A shallow groove, the *primitive groove*, appears on the surface of the streak, and the cephalic end of this groove communicates with the archenteron through an aperture named the *blastopore*. The primitive streak is produced by a thickening of the axial part of the ectoderm, the cells of which multiply and blend with those of the subjacent entoderm (fig. 76, III, IV, V). From the primitive streak a third layer of cells, the *mesoderm*, extends between the ectoderm and entoderm.

The extension of the mesoderm takes place throughout the whole of the embryonic and extra-embryonic areas of the ovum, except in certain regions. One of these is seen at the cephalic end of the neural tube. Here the mesoderm grows forwards

FIG. 75.—An embryo of Hylobates concolor. Dorsal aspect, with the amnion laid open. (After Selenka.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

in the form of two crescentic masses, which meet in the middle line so as to enclose an area which is devoid of mesoderm. Over this area the ectoderm and entoderm are in contact with each other and constitute a thin membrane, the *buccopharyngeal membrane*, which forms a septum between the stomodœum or primitive mouth and the fore-gut or head-end of the primitive digestive tube. Where the lateral crescents of mesoderm meet in front of the buccopharyngeal membrane, the pericardium is afterwards developed, and this region is therefore designated the *pericardial area*. At the hind end of the embryo the ectoderm and entoderm are also in contact, and here they form the *cloacal membrane*.

The embryonic disc now consists of three layers, named from without inwards, ectoderm, mesoderm, and entoderm; each has distinctive characteristics and gives rise to certain tissues of the body.

The **ectoderm** consists of columnar cells, which are, however, somewhat flattened or cubical towards the margin of the embryonic disc. It forms the whole of the nervous system, the epidermis of the skin, the lining cells of the sebaceous, sudoriferous and mammary glands, the hairs and nails, the epithelium of the nose and adjacent air-sinuses, and that of the cheeks and roof of the mouth. From it

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

also are derived the anterior lobe of the hypophysis cerebri, the epithelium of the cornea, conjunctiva, and lacrimal glands, the neuro-epithelium of the sense-organs, and the enamel of the teeth.

FIG. 76.—A series of transverse sections through the embryonic disc of Tarsius. (After Hubrecht.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

Section I passes through the disc, in front of Hensen's knot, and shows only the ectoderm and entoderm. Sections II, III, and IV pass through Hensen's knot, which is seen in V tapering away into the primitive streak. In III, IV, and V the mesoderm is seen springing from the keel-like thickening of the ectoderm, which in III and IV is observed to be continuous into the entoderm.

The **entoderm** consists at first of flattened cells, which subsequently become columnar. It forms the epithelial lining of the whole of the digestive tube excepting part of the mouth and pharynx and the terminal part of the rectum (which are lined by involutions of the ectoderm), the lining cells of all the glands which open into the digestive tube, including those of the liver and pancreas, the epithelium of the auditory tube and tympanic cavity, of the trachea, bronchi, and air-cells of the lungs, of the urinary bladder and part of the urethra, and that which lines the follicles of the thyreoid gland and thymus.

FIG. 77.—A diagram showing the extension of the mesoderm.

The **mesoderm** consists of loosely arranged branched cells surrounded by a considerable amount of intercellular fluid. From it the remaining tissues of the body are developed. The endothelial lining of the heart and blood-vessels and the blood-corpuscles are, however, regarded by some as being of entodermal origin.

As the mesoderm spreads between the ectoderm and entoderm it is separated for a time into lateral halves by the neural tube and notochord, presently to be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

described. A longitudinal groove appears on the dorsal surface of either half and divides it into (*a*) the *paraxial mesoderm* which adjoins the neural tube and notochord, and is subsequently divided into the primitive segments, and (*b*) a lateral portion, the *lateral mesoderm*. The mesoderm in the floor of the longitudinal groove between the paraxial and the lateral mesoderm, is known as the *intermediate cell-mass;* the genito-urinary organs are developed in it, and for this reason it is sometimes named the *nephrogenic cord*. The lateral mesoderm splits into two layers, an outer or *somatic*, which adheres to the outer surface of the ectoderm of the amniotic vesicle, and extends on to the inner surface of the trophoblast now developing into the chorion; and an inner or *splanchnic*, which adheres to the entoderm, and with it forms the *splanchnopleure* (figs. 79, 82). The space between the two layers of the mesoderm is termed the *cœlom*. The intra-embryonic part of the cœlom forms the pericardial, pleural and peritoneal cavities; the extra-embryonic part is obliterated (p. 61).

THE NEURAL GROOVE AND TUBE

Anterior to the cephalic end of the primitive streak two longitudinal ridges, caused by a thickening and upfolding of the ectoderm, make their appearance, one on either side of the middle line (fig. 79). These are named the *neural folds*; they commence near the cephalic end of the embryonic disc, where they are continuous with each other, and gradually extend caudalwards, one on either side of the primitive streak. Between the neural folds is a shallow median groove, the *neural groove* (figs. 79, 80). This groove gradually deepens, and the edges of the folds meet and coalesce in the middle line and convert it into a closed tube, the *neural tube or canal* (fig. 82), the ectodermal wall of which forms the rudiment of the nervous

Fig. 78.—Two stages in the development of the neural crest in the human embryo. (Lenhossék.)

system. By the coalescence of the neural folds over the anterior end of the primitive streak, the blastopore no longer opens on the dorsal surface of the embryo but into the neural tube, and thus a transitory canal, the *neurenteric canal*, is established between the neural and primitive digestive tubes. Closure of the neural groove occurs first in the region of the hind-brain, and from there extends forwards and backwards; towards the end of the third week the anterior opening (*anterior neuropore*) of the tube closes, and forms a recess which is in contact, for a time, with the overlying ectoderm; about the same time the posterior opening or *posterior neuropore* is closed. Subsequently the paraxial mesoderm grows round the neural tube, and separates it from the overlying ectoderm.

Before the neural groove is closed a ridge of ectodermal cells appears along the margin of either neural fold; this is termed the *neural crest* or *ganglion-ridge* (fig. 78),

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and from it the spinal and cerebral nerve-ganglia, the ganglia of the sympathetic nervous system, and the chromaffin bodies are developed.

The cephalic end of the neural groove exhibits several dilatations which, when the neural tube is closed, assume the form of three vesicles; these constitute the three primary cerebral vesicles, and correspond respectively to the future *prosencephalon* (fore-brain), *mesencephalon* (mid-brain), and *rhombencephalon* (hind-brain) (fig. 81). The walls of the vesicles are developed into the nervous tissue and neuroglia of the brain, and the cavities of the vesicles are modified to form the ventricles of the brain. The remainder of the neural tube forms the *medulla spinalis* or *spinal cord*; from its ectodermal wall the nervous and neuroglial elements are formed and its cavity persists as the central canal of the medulla spinalis.

FIG. 79.—A series of transverse sections through the embryo of a dog. (After Bonnet.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

Section I is the most anterior. In V the neural plate is spread out nearly flat. The series shows the uprising of the neural folds to form the neural canal.

a, aortæ; *c*, intermediate cell-mass; *ect*, ectoderm; *ent*, entoderm; *h*, *h*, rudiments of endothelial heart-tubes. In III, IV, and V the scattered cells represented between the entoderm and splanchnic layer of mesoderm are the vasoformative cells which give origin in front, according to Bonnet, to the heart tubes *h*: *l.p.*, lateral plate still undivided in I, II, and III; in IV and V split into somatic (*sm*) and splanchnic (*sp*) layers of mesoderm; *mes*, mesoderm; *p*, pericardium; *so*, primitive segment.

THE NOTOCHORD

The **notochord** (fig. 82) constitutes the foundation of the axial skeleton, since around it the segments of the vertebral column are formed; its appearance synchronises with that of the neural tube. It grows forwards as a rod of cells (probably of mesodermal origin) from the cephalic end of the primitive streak, and is at first intimately connected with the entoderm underlying the neural groove. It soon separates from the entoderm, and the separation is later emphasised by the meso-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

derm which grows medialwards and surrounds it. When fully formed the notochord extends throughout the length of the future vertebral column, and its cephalic end reaches as far as the anterior part of the mid-brain, where it ends in a hook-like extremity in the region of the future dorsum sellæ of the sphenoidal bone. From the mesoderm surrounding the neural tube and notochord, the skull, the vertebral column, and the membranes of the brain and medulla spinalis are developed.

THE PRIMITIVE SEGMENTS

Towards the end of the third week transverse segmentation of the paraxial mesoderm begins, and converts it into a series of well-defined, more or less cubical masses, the *primitive segments* (figs. 81, 82, 83), which extend from the occipital region of the skull along the entire length of the trunk on either side of the middle line. Each segment originally contains a central cavity (*myocœl*), but this is soon filled with angular and spindle-shaped cells.

The primitive segments lie immediately under the ectoderm on the lateral aspect of the neural tube and notochord, and are connected to the lateral mesoderm by the *intermediate cell-mass*. Those of the trunk are divisible into the following groups

FIG. 80.—A human embryo, 2 mm. in length. Dorsal aspect, with the amnion laid open. × 30. (After Graf Spee.)

viz.: cervical 8, thoracic 12, lumbar 5, sacral 5, and coccygeal from 8 to 10. Those of the occipital region of the head are usually described as being four in number. In mammals primitive segments of the head can only be recognised in the occipital region, but a study of the lower vertebrates leads to the belief that they are present also in the anterior part of the head, and that altogether nine segments are represented in the head region.

THE FORMATION OF THE EMBRYO

The embryo increases rapidly in size, but the circumference of the embryonic disc, or line of meeting of the embryonic and amniotic parts of the ectoderm, is of relatively slow growth and gradually forms a constriction between the embryo and the greater part of the archenteron. By means of this constriction, which corresponds to the future umbilicus, the dorsal part of the archenteron is enclosed

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

within the embryo and constitutes the *primitive digestive tube*; the ventral part is left outside the embryo and constitutes the *yolk-sac*.

The embryo grows more rapidly in length than in width, and its cephalic and caudal ends bend in a ventral direction to form the *cephalic and caudal folds* respectively (figs. 89, 90). The cephalic fold is first formed, and the forward growth of

FIG. 81.—A chick embryo thirty-three hours old. Dorsal aspect. × 30. (From Duval's Atlas d'Embryologie.)

the head necessarily carries with it the posterior end of the pericardial area, so that this area and the buccopharyngeal membrane are folded under the head of the embryo. A diverticulum of the archenteron, named the *fore-gut*, is enclosed in the cephalic fold. The caudal end of the embryo is connected to the chorion by a band of mesoderm called the *body-stalk*, but with the continued growth of this end and the formation of the caudal fold the body-stalk assumes a ventral position; a diverticulum of the archenteron extends into the caudal fold and is termed the *hind-gut*. Between the fore-gut and the hind-gut there exists for a time a wide

CC10. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

opening into the yolk-sac, but the relatively slow growth of the latter reduces it to a small pear-shaped sac (sometimes termed the *umbilical vesicle*), and the channel of communication is at the same time elongated to form a narrow tube called the *vitelline duct*.

THE YOLK-SAC

The **yolk-sac** (figs. 84, 85) is situated on the ventral aspect of the embryo; it is lined with entoderm, outside of which is a layer of mesoderm. It is filled with *vitelline*

FIG. 82.—A transverse section through a ferret embryo. (A. Robinson.)

fluid, which is possibly utilised for the nourishment of the embryo during the earlier stages of its existence. Blood is conveyed to the wall of the sac by the ventral branches of the primitive aortæ, and, after circulating through a wide-meshed

FIG. 83.—A human embryo, 2·1 mm. long. Dorsal aspect. (From a model by Eternod.)

capillary plexus, is returned by the vitelline veins to the tubular heart of the embryo. By means of this circulation nutritive material is absorbed from the yolk-sac and conveyed to the embryo. At the end of the fourth week the yolk-sac presents the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

appearance of a small pear-shaped vesicle (umbilical vesicle) opening into the digestive tube by a long narrow tube, the *vitelline duct*. The vitelline duct loses its attachment to the digestive tube, and as a rule undergoes complete obliteration during the seventh week, but in about two per cent. of cases its proximal part persists as a diverticulum (*Meckel's diverticulum*) from the small intestine, situated

FIG. 84.—A sagittal section through the embryo which is represented in fig. 80. (After Graf Spee.)

FIG. 85.—A human embryo of 2·6 mm. in length. Lateral aspect. (His.)

about one metre above the ileocolic junction, and sometimes attached by a fibrous cord to the abdominal wall at the umbilicus. A narrowing of the lumen of the ileum is occasionally found opposite the site of attachment of the duct.

The umbilical vesicle can be seen in the after-birth as a small somewhat oval-shaped body with a diameter of from 1 to 5 mm.; it is situated between the amnion and the chorion, and may lie on, or at a variable distance from, the placenta.

THE FŒTAL MEMBRANES AND THE PLACENTA

The **allantois** (figs. 84, 90, 93).—The allantois arises as a tubular diverticulum the posterior part of the archenteron; when the hind-gut is developed the allanto is carried backwards with it, and then opens from the cloaca or terminal part

FIG. 86.—A fœtus of about eight weeks, enclosed in the amnion. Magnified a little over 2 diameters. Drawn from stereoscopic photographs lent by Prof. A. Thomson, Oxford.

the hind-gut: it extends into the mesoderm of the body-stalk which connects th tail-end of the embryo with the chorion. The allantoic diverticulum is lined wit entoderm and covered with mesoderm, and in the latter are umbilical vessels.*

* In reptiles, birds, and many mammals the allantois expands into a vesicle which projec into the extra-embryonic cœlom. If its further development be traced in the bird, it is seen project to the right side of the embryo, and, gradually expanding, spreads over the dorsal surfa of the embryo as a flattened sac between the amnion and the serosa (p. 60*), and ultimate surrounds the yolk. Its outer wall becomes applied to, and fuses with, the serosa which li immediately inside the shell membrane. Blood is carried to the allantoic sac by the tw allantoic or umbilical arteries, which are continuous with the primitive aortæ, and after circ lating through the allantoic capillaries, is returned to the primitive heart by the two umbilic veins. In this way the allantoic circulation, which is of the utmost importance in connexi with the respiration and nutrition of the chick, is established. Oxygen is taken from, an carbonic acid is given up to the atmosphere through the egg-shell, and nutritive materials a at the same time absorbed by the blood from the yolk. With the formation of the amnion t embryo is, in most animals, entirely separated from the chorion, and is only again united the chorion when the allantoic mesoderm spreads over and becomes applied to its inner surfac but the human embryo, as was pointed out by His, is never wholly separated from the chori its tail-end being from the first connected with the chorion by means of a thick band of mesoder named the *body-stalk*.

The **amnion** is a membranous sac which surrounds and protects the embryo; it is developed in reptiles, birds, and mammals, but not in amphibia or fishes.

In the human embryo the earliest stages of the formation of the amnion have not been observed; in the youngest embryo which has been studied the amnion was

FIG. 92.—A transverse section through the umbilical cord.

already present as a closed sac (figs. 87, 94), and, as indicated on page 49, appears as a cavity in the ectodermal part of the inner cell-mass. This cavity is roofed in by a stratum of flattened ectodermal cells, the *amniotic ectoderm*, and its floor consists of the prismatic ectoderm of the embryonic disc—the continuity between the roof and floor being established at the margin of the embryonic disc.

FIG. 93.—A human embryo, 1·3 mm. long. (From a model by Eternod.)

Outside the amniotic ectoderm is a thin layer of mesoderm, continuous with that of the somatopleure and connected by means of the body-stalk with the mesodermal lining of the chorion.*

* In reptiles, birds, and many mammals the amnion is developed as follows:—At the constriction where the primitive digestive tube of the embryo joins the yolk-sac, a reflection or upfolding of the somatopleure takes place. This, the *amniotic fold*, first makes its appearance at the cephalic end, and subsequently at the caudal end and sides of the embryo, and gradually rising more and more its different parts meet and fuse over the dorsal surface of the embryo, and enclose a cavity, the *amniotic cavity*. After the fusion of the edges of the amniotic fold, the two layers of the fold separate; the inner forms the *amnion*, the outer, the *false amnion* or *serosa*. The space between the amnion and the serosa constitutes the extra-embryonic cœlom, and for a time communicates with the embryonic cœlom.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Fluid, termed *liquor amnii*, appears within the amnion and increases steadily in amount, so that the sac gradually expands and encroaches on the cavity of the extra-embryonic cœlom; this expansion continues until the extra-embryonic cœlom is obliterated. The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, and then diminishes somewhat; at the end of pregnancy it amounts to about 1 litre. It allows of the free movements of the fœtus during the later stages of pregnancy, and also diminishes the risk to the fœtus of injury from without. It contains less than two per cent. of solids, consisting of urea and other extractives, inorganic salts, a small amount of protein, and frequently a trace of sugar.

FIG. 94.—A section through an ovum imbedded in the uterine decidua. Semidiagrammatic. (After Hubert Peters.)

The **body-stalk** and the **umbilical cord**.—The body-stalk (figs. 84, 89, 90, 93) is a band of mesoderm which first connects the tail-end of the embryo with the chorion. Extending into the proximal part of it is the canal of the allantois, and running through it from the embryo to the chorion are the umbilical vessels. Its dorsal surface is covered with the amnion and its ventral surface is bounded by the extra-embryonic cœlom. As a result of the folding of the embryo and the distension of the amnion the body-stalk comes to lie on the ventral surface of the embryo, and its mesoderm approaches that of the yolk-sac and vitelline duct (fig. 90). As a consequence of the continued expansion of the amnion, the extra-embryonic cœlom is obliterated (figs. 90, 91), the vitelline duct is elongated, and the mesoderm of the amnion blends with that of the vitelline duct and body-stalk; by this fusion a solid cord, the *umbilical cord*, is formed (fig. 91) and connects the embryo to that portion of the chorion which will form the fœtal part of the placenta.

The umbilical cord (figs. 92, 100) is enveloped by the amniotic ectoderm and consists of a core of gelatinous tissue (*jelly of Wharton*) in which the umbilical vessels, the allantoic diverticulum, and the vitelline duct and vessels are imbedded. The allantoic diverticulum and the vitelline duct and vessels undergo obliteration

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

and atrophy, but traces of them may be seen up to the fourth month of pregnancy or later. The umbilical cord becomes spirally twisted, owing, it is believed, to the unequal growth of the two umbilical arteries; it also increases in length so that at the end of pregnancy it is about 50 cm. long.

FIG. 95.—Primary chorionic villi. Diagrammatic. (Modified from Bryce.)

The **implantation or imbedding of the fertilised ovum in the uterine wall.**—As already stated (p. 46), fertilisation of the ovum is believed to occur in the lateral or ampullary end of the uterine tube, and is immediately followed by segmentation. The segmenting ovum is conveyed along the uterine tube to the cavity of the uterus.

FIG. 96.—Secondary chorionic villi. Diagrammatic. (Modified from Bryce.)

the journey occupying seven or eight days. By the time it reaches the uterus it possesses a well-developed trophoblast. The ovum adheres like a parasite to the uterine mucous membrane, destroys the epithelium over the area of contact, and excavates for itself a cavity in the mucous membrane in which it becomes imbedded. In an ovum described by Bryce and Teacher * the point of entrance of the ovum into

* Contribution to the study of the early development and imbedding of the human ovum, 1908.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the uterine mucous membrane was found to be closed by a mass of fibrin and leucocytes; in an ovum described by Peters * the opening was covered with a mushroom-shaped mass of fibrin and blood-clot (fig. 94), the narrow stalk of which plugged the aperture in the mucous membrane. Soon, however, all trace of the opening is lost, and the ovum is then completely surrounded by the uterine mucous membrane.

The structure actively concerned in excavating the uterine mucous membrane is the trophoblast. This increases rapidly in thickness, invades and digests the uterine tissues, destroys the epithelial cells of the uterine glands and the walls of the uterine (maternal) blood-vessels (fig. 94); at the same time there appear in the trophoblast numerous anastomosing spaces which are filled with maternal blood. These spaces expand to form what is ultimately known as the *intervillous space*, and the trophoblast is separated into a number of branching processes named the

FIG. 97.—A transverse section of a secondary chorionic villus.

primary chorionic villi (fig. 95) which are bathed in the maternal blood. Cores of mesoderm, containing branches of the umbilical vessels, soon invade the primary chorionic villi and convert them into *secondary chorionic villi* (figs. 96, 97).

The decidua.—Before the fertilised ovum reaches the uterus, the mucous membrane of the body of the uterus undergoes important changes, and is then known as the *decidua*. The thickness and vascularity of the mucous membrane are greatly increased; its glands are elongated and open on its free surface by funnel-shaped orifices, while the deeper portions of the glands are tortuous and dilated into irregular spaces. The interglandular tissue is also increased in quantity, and is crowded with large round, oval, or polygonal cells, termed *decidual cells*. These changes are well advanced by the second month of pregnancy, when the mucous membrane consists of the following strata (fig. 98): (1) *stratum compactum*, next the free surface; in this the uterine glands are only slightly expanded, and are lined by columnar cells; (2) *stratum spongiosum*, where the uterine glands are greatly dilated and very tortuous, and are ultimately separated from one another by a small amount of interglandular tissue; for a time the cells lining the glands are cylindrical, but later they become flattened; (3) a thin *limiting or boundary layer*, next the uterine muscular fibres, containing the deepest parts of the uterine glands, which are not dilated, and are lined with cubical epithelium; it is from this epithelium that the epithelial lining of the uterus is regenerated after parturition.

After the ovum is imbedded distinctive names are applied to different portions of the decidua. The part which covers the ovum is named the *decidua capsularis*; the portion between the ovum and the uterine muscular wall is named the *decidua basalis* or *decidua placentalis*, since it is here that the placenta is subsequently developed; the part which lines the remainder of the body of the uterus is known as the *decidua vera* or *decidua parietalis* (fig. 99).

* *Die Einbettung des menschlichen Eies*, 1899.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Coincidently with the growth of the embryo, the decidua capsularis is thinne and distended (fig. 99) and the space between it and the decidua vera is gradual obliterated. By the beginning of the thi month of pregnancy the decidua capsula and decidua vera are in contact; by t fifth month of pregnancy the decidua ca sularis has practically disappeared, wh during the succeeding months the decid vera also atrophies, owing to the increas pressure. The glands of the stratum co pactum are obliterated, and their e thelium is lost; in the stratum spongiosu the glands are compressed and appear slit-like fissures, and their epithelium unde goes degeneration; in the limiting boundary layer, however, the glandul epithelium retains a cubical form.

FIG. 98.—Sections of the uterine mucous membrane; (A) of the non-pregnant uterus; (B) of the pregnant uterus. Diagrammatic. (Kundrat and Engelmann.)

The **chorion** (figs. 89 to 93 and 95 to 9 consists of two layers: an outer of troph blast, and an inner of mesoderm. Th trophoblast consists of an internal layer, th *cytotrophoblast* or *layer of Langhans*, and a external layer, the *syncytiotrophoblast*. A stated (p. 63) the trophoblast undergo rapid proliferation and forms, on the su face of the chorion, numerous processes, th *primary chorionic villi* (fig. 95); these i crease in size and ramify, and the chorion mesoderm, carrying branches of the um bilical vessels, grows into them, and in th way they are converted into *seconda chorionic villi* (fig. 96). Blood is carrie from the embryo to the chorion by th umbilical arteries, and after circulatin through the capillaries of the chorionic vill is returned to the embryo by the umbilic veins. Until about the end of the secon month of pregnancy the entire chorion i covered by villi which are almost unifor in size, and project into the decidua placen talis and decidua capsularis (fig. 100). Wit the growth of the embryo and the expan sion of the amniotic cavity the decidu capsularis is thinned and compressed, th circulation through it is gradually cu off, and the villi of the corresponding par of the chorion atrophy and disappea This portion of the chorion becomes smoot (*chorion læve*); and, as it takes no shar in the formation of the placenta, is some times named the non-placental part of th chorion. On the other hand, the villi on that part of the chorion which is in conta with the decidua placentalis increase greatly in size and complexity, and hence th part is named the *chorion frondosum* (figs. 90, 91).

The **placenta** (figs. 100 to 102) connects the fœtus to the uterine wall, and is th organ by means of which the nutritive, respiratory, and excretory functions of th fœtus are carried on. It is composed of fœtal and maternal parts.

The *fœtal portion of the placenta* consists of the villi of the chorion frondosum which branches repeatedly, and increase enormously in size. The ends of some of the villi are anchored by columns of trophoblast to the walls of the intervillous space but the majority hang free in this space. All are bathed in maternal blood, which is conveyed to and from the intervillous space by the uterine vessels. Blood i carried from the embryo to the placental villi by the umbilical arteries, and returne

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to the embryo by the umbilical veins. One or two branches of an artery enter each villus and there end in a capillary plexus which is drained by one or two tributaries of the veins. The vessels of the villi are surrounded by a thin layer of mesoderm which is covered with the two strata of the trophoblast, the cytotrophoblast or layer of Langhans being in contact with the mesoderm, and the syncytiotrophoblast in contact with the maternal blood (fig. 102); after the fifth month the two strata are replaced by a single layer of somewhat flattened cells.

Fig. 99.—Diagram showing the ovum imbedded in the uterine decidua.

The *maternal portion of the placenta* is formed by the decidua placentalis containing the intervillous space. As already explained (p. 63), this space is produced by the enlargement and intercommunication of the spaces in the trophoblast; it is therefore lined throughout with syncytiotrophoblast. The formation of the intervillous space involves the disappearance of the greater portion of the stratum compactum, but the deeper part of this layer persists and is condensed to form what is known as the *basal plate*; this constitutes the outer wall of the intervillous space, and consists of a stroma containing decidual cells, portions of trophoblast and *fibrinoid substance*; the last appears to be derived in part from the trophoblast

Fig. 100.—A sectional plan of the gravid uterus in the third month. (Modified from Wagner.)

and in part from the maternal blood. Between the basal plate and the uterine muscular fibres are the stratum spongiosum and the limiting layer; through these and the basal plate the uterine arteries and veins pass to and from the intervillous space. Portions of the stratum compactum persist as pillars which project into

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the intervillous space, but these pillars do not extend as far as the chorion, exce in the marginal part of the placenta; later they form the *placental septa* whi incompletely divide the placenta into lobes or *cotyledons*.

Maternal blood is conveyed to the intervillous space by branches of the uteri arteries and carried away by tributaries of the uterine veins (figs. 101, 102). Th vessels lose their muscular coats as they enter the basal plate, and in this plate cons of sinuous channels lined only with endothelium; these channels open into intervillous space, the arteries ending near the placental septa and the veins beginn near the centres of the cotyledons. The endothelial lining of the uterine vess ends where the vessels open into the intervillous space, the latter being lined throu out with syncytiotrophoblast. The circumferential part of the intervillous sp

Fig. 101.—A fœtus in utero, between the fifth and sixth months.

consists of an irregular channel named the *marginal sinus* (fig. 102); this sin partly encircles the placenta and communicates peripherally with the uterine vei and centrally with the intervillous space; clusters of placental villi project into it.

The fœtal and maternal blood-currents do not intermingle, being separat from each other by the delicate walls of the villi. Nevertheless, the fœtal blo is able to absorb, through the walls of the villi, oxygen and nutritive materials fro the maternal blood, and give up to the latter its waste products. The blood, purified, is carried back to the fœtus by the umbilical veins. It will thus be se that the placenta not only establishes a mechanical connexion between the moth and the fœtus, but subserves for the latter the purposes of nutrition, respiratio and excretion. That the placenta possesses certain selective powers is evidenc by the fact that glucose is more plentiful in the maternal than in the fœtal blood it is interesting to note also that the proportion of iron, lime and potash in the fœt is increased during the last months of pregnancy. Further, there is evidenc that the maternal leucocytes may migrate into the fœtal blood, since leucocyt are much more numerous in the blood of the umbilical vein than in that of t umbilical arteries.

Applied Anatomy.—The placenta is usually attached near the fundus uteri, and its si corresponds with that at which the ovum is imbedded. It may, however, occupy a low

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

level, and in very rare cases occludes the internal orifice of the uterus, thus giving rise to the condition known as *placenta prævia*.

The *separation of the placenta*.—After the child is born, the placenta and membranes (the latter consisting of the amnion, the chorion læve and the superficial part of the decidua parietalis) are separated from the uterine wall and expelled as the *after-birth*. The separation takes place along the plane of the stratum spongiosum (fig. 102), and necessarily causes rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction and retraction of the uterine muscular fibres, and thus *post-partum hæmorrhage* is prevented. After the separation of the placenta and membranes a thin layer of the stratum spongiosum is left as a lining to the uterus, but this layer subsequently undergoes degeneration, and is cast off. The mucous membrane, the glands and the epithelial lining of the uterus are regenerated from the limiting or boundary layer of the decidua (p. 63).

The expelled placenta is a discoid mass which has a weight of about 500 gm., a diameter of from 15 cm. to 20 cm., and an average thickness of about 3 cm., but

Fig. 102.—A scheme of the placental circulation.

the thickness rapidly diminishes near the circumference of the placenta, which is continuous with the membranes. Its uterine or outer surface is divided by a series of fissures into lobules or *cotyledons* which are imperfectly separated from one another by the placental septa. Its fœtal or inner surface is smooth, and is closely invested by the amnion. When looked at through the amnion, the chorion presents a mottled appearance, consisting of grey, purple, or yellowish areas. The umbilical cord is usually attached near the centre of the placenta, but may be inserted at any point between the centre and the margin; in some cases it is inserted into the membranes, i.e. the *velamentous* insertion. From the site of the attachment of the cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper and larger than the arteries. The remains of the vitelline duct and yolk-sac may be sometimes observed beneath the amnion, close to the cord, the former as an attenuated thread, the latter as a minute sac.

On section, the placenta presents a soft, spongy appearance, caused by the greatly branched villi; these are surrounded by a varying amount of maternal blood which gives the dark red colour to the placenta.

The further growth of the embryo will be best understood from a description of the principal facts relating to the development of the chief systems of which the body consists.

THE DEVELOPMENT OF THE PARIETES

The **skeleton** is of mesodermal origin, and may be divided into (1) th axial skeleton, viz. that of the vertebral column, skull, ribs, and sternu and (2) the appendicular skeleton, viz. that of the limbs.

The **vertebral column.**—The notochord (fig. 82) is a temporary structure a forms a central axis, around which the segments of the vertebral column a developed.* The notochord is derived from the cephalic end of the primiti streak, and, when fully formed, consists of a rod of cells, which lies on the vent aspect of the neural tube and reaches from the anterior end of the mid-brain the extremity of the tail. On either side of it is a column of paraxial mesode which becomes subdivid into a number of more less cubical segments, t *primitive segments* (figs. 8 83). These are separat from one another by *inte segmental septa* and a arranged symmetrically either side of the neura tube and notochord: t each primitive segment spinal nerve is distribute At first each segment co tains a central cavity, th *myocœl*, but this is soo filled with a core of angul and spindle-shaped cell The cells of each segme are differentiated into thr groups, which form respe tively the cutis-plate dermatome, the muscl plate or myotome, and th sclerotome (fig. 103). Th *cutis-plate* is placed on th lateral and dorsal aspec of the myocœl, and fro it the true skin of th corresponding segment derived; the *muscle-plat* is situated on the medi side of the cutis-plate, an furnishes the muscles the segment. The cells of the *sclerotome*, largely derived from those formin the core which fills the myocœl, lie next the notochord. Fusion of the individu sclerotomes in an anteroposterior direction soon takes place, and thus a co tinuous strand of cells, the *scleratogenous layer*, is formed along the ventr lateral aspect of the neural tube. The cells of this layer proliferate rapidly, an extending medialwards surround the notochord; at the same time they gro backwards on the lateral aspects of the neural tube and eventually surround and thus the notochord and neural tube are enveloped by a continuous shea of mesoderm (fig. 105, A), which is termed the *membranous vertebral column.* this mesoderm the original sclerotomes are still distinguishable, but each is no differentiated into two portions, an anterior, consisting of loosely arranged cells, an a posterior, of more condensed tissue (fig. 104, A and B). Between the two portio the rudiment of the intervertebral fibrocartilage is laid down (fig. 104, C). Cel from the posterior mass grow into the intervals between the myotomes (fig. 104, and C) of the corresponding and succeeding segments, and extend both dorsall

and ventrally; the dorsal extensions surround the neural tube and represent the future vertebral arch, while the ventral extend into the body-wall as the costal processes. The hinder part of the posterior mass joins the anterior mass of the succeeding sclerotome to form the vertebral body. Each vertebral body is therefore

FIG. 104.—A scheme showing the manner in which each vertebral body is developed from portions of two adjacent segments.

a composite of two segments, being formed from the posterior portion of one and the anterior part of that immediately behind it. The vertebral and costal arches are derivatives of the posterior part of the segment in front of the intersegmental septum with which they are associated.

This stage is succeeded by that of the *cartilaginous vertebral column*. In the fourth week cartilaginous centres make their appearance on either side of the notochord; these extend round the notochord and form the bodies of the cartilaginous vertebræ. A pair of cartilaginous foci appear in the lateral parts of each vertebral arch, and grow backwards on either side of the neural tube to form the cartilaginous vertebral arch, and a separate cartilaginous centre appears for each costal process. In the eighth week the cartilaginous vertebral arch fuses with the

FIG. 105.—Diagrams showing (A) the membranous and (B) the cartilaginous stages of a typical vertebra.

cartilaginous body, and in the fourth month the halves of the arch unite on the dorsal aspect of the neural tube (fig. 105, B); the spinous process is developed from the junction of the halves of the vertebral arch. The transverse processes grow out from the vertebral arch behind the costal processes.

In the upper cervical vertebræ a band of mesodermal tissue, named the *hypochordal bar* (fig. 106, A), connects the ventral ends of each vertebral arch across the ventral surface of the intervertebral fibrocartilage. In all except the atlas or first cervical vertebra this bar is transitory and fuses with the intervertebral fibro-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

cartilage. In the atlas it persists, undergoes chondrification, and develops into th anterior arch of this bone, while the cartilage representing the body of the atla forms the dens or odontoid process which fuses with the body of the epistrophe or second cervical vertebra (fig. 106, B).

Fig. 106.—Diagrams showing the transformation of the hypochordal bar into the anterior arch of the atlas.

The portions of the notochord contained within the bodies of the vertebr atrophy, and ultimately disappear, while the portions in the centres of the inter vertebral fibrocartilages expand, and persist throughout life as the central *nucleu pulposus* of each fibrocartilage (fig. 107).

The **ribs.**—The ribs are formed from the costal processes of the primitive vertebr arches, the processes extending between the muscle-plates. In the *thoracic regi* of the vertebral column the costal processes grow lateralwards to form a seri of arches, the *primitive costal arches.* The transverse process grows out behi the vertebral end of the costal process, and is at first connected to this proce by mesoderm which is later differentiated to form the costotransverse ligament between the costal process and the tip of the transverse process the costotransver

Fig. 107.—A sagittal section through an intervertebral fibrocartilage and the adjacent parts of two vertebræ of the embryo of a sheep. (Kölliker.)

joint is formed by absorption, while the proximal end of the costal process becom separated from the vertebral arch by the development of the costocentral joi In the *cervical vertebræ* (fig. 108) the transverse process forms the posterior bounda of the foramen transversarium, while the costal process, corresponding to the he and neck of the rib, remains in continuity with the body of the vertebra, and for the anterolateral boundary of this foramen. The distal portions of the primiti costal arches remain undeveloped; occasionally, however, the costal processes of t seventh cervical vertebra undergo greater development, and by the formation costovertebral joints are separated off as cervical ribs. In the *lumbar region* the dist portions of the primitive costal arches fail; the proximal portions fuse with t

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

transverse processes to form the transverse processes of descriptive anatomy. Occasionally a pair of movable ribs is developed in connexion with the first lumbar vertebra. In the *sacral region* costal processes are developed only in connexion with the upper three or four vertebræ; the processes of adjacent segments fuse with one another to form the lateral parts of the sacrum. The *coccygeal vertebræ* are devoid of costal processes.

FIG. 108.—Diagrams showing the portions of the adult vertebræ derived respectively from the bodies, vertebral arches, and costal processes of the embryonic vertebræ.

The bodies of the vertebræ are represented in yellow, the vertebral arches in red, and the costal processes in blue.

CERVICAL

LUMBAR

THORACIC

SACRAL

The **sternum.**—The ventral ends of the ribs become united to one another by a longitudinal bar termed the *sternal plate*, and opposite the first seven pairs of ribs these sternal plates fuse in the middle line to form the manubrium and body of the sternum. The xiphoid process is formed by a backward extension of the sternal plates.

The **skull.**—The bones of the cranium are developed from the mesoderm which invests the cerebral vesicles. At the end of the first and beginning of the second month of fœtal life this mesoderm increases in thickness and forms masses of blastema. These masses represent the earliest distinguishable elements of the skeleton of the head, and first become evident in the occipital region where they form a plate, the so-called *occipital plate*; in the middle of this plate the notochord runs sagitally. The occipital plate sends out on either side two processes which surround the hypoglossal nerve and form the hypoglossal canal.

The occipital plate is continued forwards as a thin blastemal layer on the dorsal aspect of the pharynx, and reaches the rudiment of the hypophysis. At the beginning of the second month it surrounds the duct of the hypophysis and extends between the nasal fossæ where it forms the basis of the ethmoidal bone and the nasal septum.

About the fifth week the two auditory vesicles become enclosed in blaste capsules, each of which is soon differentiated into a dorsolateral part envelo the semicircular canals, and a ven medial part surrounding the cochl at the upper boundary between th two parts the facial nerve lies i deep groove. The blastemal audit capsules fuse with the lateral proce of the occipital plate, leaving, h ever, a wide gap between each cap and the more median part of occipital plate; through this gap internal jugular vein, and the glos pharyngeal, vagus and accessory c bral nerves are transmitted.

FIG. 109.—A sagittal section through the cephalic end of the notochord. (Keibel.)

At this stage the blastema which s rounds the hypophysial duct and fo the rudiment of the post-sphenoi part of the body of the sphenoi bone, sends out a wing-like proc on either side, the future great wi (ala magna). More anteriorly, fro the central blastema which is form the interorbitonasal septu processes extend laterally and indic the sites of the small wings (a parvæ) of the sphenoidal bone, while condensations occur on either side of the na fossæ and blend above with the blastemal septum.

The first indications of the vault of the skull are seen about the thirtieth d and consist of blastemal plates which appear at the sides of the head and gradua extend into the upper wall where they blend with one another; they also ble with the blastema at the base of the cranium.

In the shark and dogfish this blastemal cranium undergoes complete chondrifi tion and forms the cartilaginous skull or chondrocranium of these animals. mammals the process of chondrification is limited to the base of the skull, includi a region dorsal to the foramen magnum and the auditory capsules. Chondrificati takes place primarily in two regions: (*a*) the anterior or *prechordal* part is developed front of the notochord and shows no regular division into primitive segments; (*b*) posterior or *chordal* part of the base of the skull is developed from the blastema wh surrounds the notochord, and exhibits traces of four primitive segments separat from one another by the roots of the hypoglossal nerve. (In the spring squirrel the is definite evidence that five primitive segments enter into the posterior part, as the are four separate roots of the hypoglossal nerves, and four hypoglossal canals.)

In mammals chondrification takes place primarily in three regions; (*a*) posteri in relation to the notochord; (*b*) intermediate, in relation to the hypophysis; a (*c*) anterior, between the orbital cavities and the nasal cavities. These parts may named *chordal*, *hypophysial*, and *interorbitonasal*; perhaps the last is identical with t trabeculæ cranii of the majority of vertebrates lower than mammals. It is uncert what the hypophysial part represents; when ossified it forms the postsphenoid.

* In man chondrification of the skull (figs. 110, 111, 112, 113) begins in the seco month of fœtal life, even before the blastemal stage is completed, and the first nu appear in the occipital plate, one on either side of the notochord, medial to hypoglossal canal. About the thirty-sixth day these two nuclei fuse anteriorly the dorsal surface of the notochord, and later they fuse posteriorly on its vent surface. Thus the notochord lies dorsal to the caudal part of the cartilagin occipital plate, then traverses the plate and lies ventral to it, and finally passes front of it and ends on the dorsal surface of the post-sphenoidal cartilage (fig. 10

The posterior part of the sphenoidal cartilage chondrifies from two centres, on either side of the developing hypophysis; these unite first behind and then front of the duct of the hypophysis, and in this way the craniopharyngeal can

* The following description is mainly based on the researches of Professor E. Fawcett. T reader is referred for further details to the *Journal of Anatomy and Physiology*, volumes xlv. and lii., and to the *Proceedings of the Anatomical Society of Great Britain and Ireland*, 1916.

Digitized by Arya Samaj Foundation Chennai and eGangotri

through which the hypophysial diverticulum ascends into the skull, is formed; this canal is usually obliterated at the third month, but may remain open.

The central blastema in front of the hypophysis undergoes independent chondrification; it speedily joins with the posterior end of the chondrifying interorbitonasal septum, and from these are subsequently developed the presphenoidal part of the sphenoidal bone and the bony (ethmoidal) part of the nasal septum. All the above-mentioned parts ultimately fuse and form a continuous cartilaginous stem from the anterior edge of the foramen magnum to the anterior end of the nose.

The blastemal auditory capsule next undergoes chondrification, the portion surrounding the semicircular canals (canalicular portion) chondrifying before that enveloping the cochlea. A plate of cartilage (parietal plate) is connected to the

FIG. 110.—The chondocranium of a human embryo of a crown-rump length of 27 mm. Superior aspect. (From a model prepared by Prof. Edward Fawcett and Gwladys Ruth Llewelyn, B.Sc.)

top of the canalicular part of each auditory capsule by means of a cartilaginous commissure. At the third month this plate forms a considerable part of the side-wall of the cranium, and is separated by only a small interval from the hinder end of the small wing of the sphenoidal bone. The distance between the two rapidly increases as age advances owing to the disappearance of the cartilage.

It is highly probable that the roof of the cranium in its typical human condition is formed by three tecta, which may be called the *tectum posterius*, *tectum intermedium*, and *tectum anterius*. The tectum posterius is broadest from above downwards, and when ossified forms the supra-occipital segment of the occipital bone. The tectum intermedium is very narrow and lies immediately in front of the tectum posterius; it soon disappears, and may not even form. The tectum anterius which stretches between the two parietal plates is a compound structure consisting of two lateral pieces, one on each side, and a median unpaired segment.

he post-sphenoidal cartilage and the corresponding great wing with the anterior nd of the cochlear capsule, lateral to the carotid artery. These nuclei form, on ither side, the alar process which later ossifies as the lingula. The cartilaginous reat wing is smaller than the small wing and only gives rise to the root of the terygoid process and to that part of the bone which surrounds the maxillary livision of the trigeminal nerve.

Between the great wing and the auditory capsule is a wide space which lodges he semilunar (Gasserian) ganglion and transmits the mandibular division of the rigeminal nerve and the middle meningeal artery. The backward growth of the alar rocess cuts off this space from the carotid canal, and at a later date the mandibular erve and middle meningeal artery are surrounded by membrane bone. The space etween the great and small wings forms the superior orbital (sphenoidal) fissure.

Chondrification of the small wing begins lateral to the optic nerve, and from this entre ingrowths extend in front of and behind the optic nerve and fuse with the inder part of the interorbitonasal septum and so form the optic foramen. Ossification of the small wing begins just lateral to the optic foramen, but does not extend ery far out; a considerable part of the cartilage disappears, and owing to this, the mall wing, in the bony condition, is much smaller than the great wing.

The *nasal capsule* is situated in front of the small wings, and is well developed y the third month; it consists of a central part, or septum, and two lateral parts.

The septum lies partly under the brain (subcerebral) and partly in front of the rain (precerebral); its lower margin is almost horizontal and is, for a time, free; s anterior border intervenes between the anterior nares (fenestræ narinæ).

The lateral parts of the capsule are primarily suspended from the precerebral part of the septum; later they are connected with the subcerebral part of the eptum by the lamina cribrosa of the ethmoidal bone. Each lateral part consists

FIG. 113.—The nasal capsule of a human embryo 65 mm. long. Ventral aspect. On the left side the floor of the capsule has been removed. (From a model by Professor Edward Fawcett.)

of an anterior, an intermediate and a posterior portion. The anterior and intermediate portions are separated externally by an anterolateral sulcus which corresponds internally with a semilunar crest; the lower end of this crest forms the uncinate process of the ethmoidal bone. The posterior and intermediate portions are separated by a faint postero-lateral sulcus which corresponds internally with the middle nasal concha. The lower edge of the lateral wall of the capsule is incurved to form the inferior nasal concha which, at the fifth month, becomes ossified and detached from the lateral wall of the capsule.

In man the floor of the cartilaginous nasal capsule is far from complete (fig. 113). In rodents and some marsupials it consists of an anterior and a posterior transverse

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

lamina connecting the lateral wall of the capsule with the septum; in front of anterior lamina is the fenestra narina. The anterior and posterior transverse lam are connected by a bar of cartilage which runs backwards alongside the sept and forms the *common paraseptal cartilage*; the anterior part of this cartilag bilaminar, and between the laminæ the organ of Jacobson is lodged; the poste part is small and cylindrical.

In man the greater part of the anterior transverse lamina is absent and thus fenestra narina is continuous with the fenestra basalis, the two forming the fiss rostroventralis. Further, only the anterior and posterior segments of the com paraseptal cartilage are developed in man; these parts are termed the anterior posterior paraseptal cartilages and are united to one another by fibrous membran

Part of the cartilaginous capsule is ossified to form the ethmoidal bone and inferior nasal conchæ, part remains cartilaginous as the septal and alar cartila of the nose, and part is replaced by membrane bones.

The ventral surface of the chondrocranium is indirectly connected with cartilages of the visceral arches, the fate of which is described below.

The bones of the vault of the skull are of membranous formation, and are term *dermal or covering bones*. They comprise the frontal and parietal bones, the up part of the squama occipita (interparietal bone), and squamæ and tympanic parts the temporal bones. During th course of growth cartilage a pears in the articular tuber (eminentia articularis) of temporal bone. Some of dermal or covering bones rem distinct throughout life (e parietal and frontal), while oth join with the bones of the ch drocranium (e.g. interparietal a squamæ of temporals).

FIG. 114.—A human embryo between eighteen and twenty-one days. Left lateral aspect. (His.)

The **branchial or visceral arch and pharyngeal pouches.**—In t lateral walls of the anterior p of the fore-gut five *pharyng pouches* appear (figs. 115, 11 each of the upper four pouches prolonged into a dorsal and ventral diverticulum. Over the pouches corresponding indent tions of the ectoderm occ forming what are known as t *branchial or outer pharyng grooves*. The mesoderm which intervenes between the pouches and the grooves pressed aside for a time, and the ectoderm unites with the entoderm of the fore-g along the floors of the grooves to form thin *closing membranes* between the fore-g and the exterior; the mesoderm again penetrates between the entoderm and t ectoderm of these closing membranes. In gill-bearing animals the closing me branes disappear, and the grooves become the gill-clefts. Perforation does n occur in birds or mammals.

The branchial grooves separate a series of rounded bars or arches, the *branch or visceral arches* in which thickening and consolidation of the mesoderm take pla (figs. 114 to 116). The dorsal ends of these arches are attached to the sides of t head, while the ventral ends ultimately meet in the middle line of the neck. all, six arches make their appearance, but of these only the first four are visi externally. The first arch is termed the mandibular, and the second the hyoi the others have no distinctive names. In each arch the central part of the mesode consolidates and is then converted into a cartilaginous bar, consisting of right a left halves. Moreover, each arch is traversed by a nerve and by one of the primiti aortic arches.

The *mandibular arch* lies between the stomodæum or primitive mouth and t first branchial groove; from it are developed the lower lip, the mandible, the musc

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of mastication, and the anterior part of the tongue. Its cartilaginous bar is formed by what are known as *Meckel's cartilages* (right and left) (fig. 117). The dorsal end of each cartilage is ossified to form two of the three bones of the middle ear, viz. the malleus and incus; the ventral ends of the two cartilages meet in the region of the symphysis menti, and become ossified and incorporated with that part of the mandible which lies below and inside the medial and lateral incisors (Low). The portion immediately below the malleus and incus is replaced by fibrous membrane which constitutes the sphenomandibular ligament, while the mandible is ossified in the connective tissue covering the remainder of the cartilage. From the dorsal ends of the mandibular arch a triangular process, the *maxillary process*, grows forwards on either side and forms the lower eyelid, the cheek, the lateral part of the upper lip, the zygomatic bone, and the greater part of the maxilla.

FIG. 115.—The head-end of a human embryo, about the end of the fourth week. Left lateral aspect. (From a model by Peter.)

The second or *hyoid arch* assists in forming the side and front of the neck. From the dorsal end of its cartilaginous bar the third bone of the middle ear, viz. the stapes, is developed, and subsequently becomes attached to the auditory capsule. From the ventral part of the arch the styloid process, stylohyoid ligament, and lesser cornu of the hyoid bone are developed; the glossopalatine arch indicates the position of the hyoid arch. The cartilage of the *third arch* gives origin to the greater cornu of the hyoid bone, and the ventral ends of the second and third arches unite with those of the opposite side, and form a transverse band, from which the body of the hyoid bone and the posterior part of the tongue are developed. From the cartilage of the *fourth arch* the thyreoid cartilage is developed; from the cartilages of the *fifth arch* the cricoid cartilage is formed (Fawcett).*

FIG. 116.—The floor of the pharynx of the embryo shown in fig. 115.

The mandibular and hyoid arches grow more rapidly than those behind them, with the result that the third and fourth arches recede from the surface and form the floor of a deep depression, the *sinus cervicalis*. The hyoid arch grows backwards and overlaps the sinus, the opening from which assumes the form of a narrow duct; this duct closes and converts the sinus into a vesicle which disappears before the end of the second month.

From the first branchial groove the concha of the auricula and the external acoustic meatus are developed, while around the groove there appear, on the mandibular and hyoid arches, several swellings from which the auricula or pinna is formed (p. 108). From the upper or dorsal parts of the first and second pharyngeal pouches the auditory tube and the tympanic cavity are developed (p. 107); the closing membrane between the mandibular and hyoid arches is invaded by mesoderm, and forms the tympanic membrane. No traces of the

second, third, or fourth branchial grooves persist. The dorsal angle of the sec pharyngeal pouch is named the *sinus tonsillaris*; in it the tonsil is developed, above the tonsil a trace of the sinus persists as the supratonsillar fossa.

FIG. 117.—The head and neck of a human embryo, eighteen weeks old, with Meckel's cartilage and the hyoid bar exposed. (After Kölliker.)

pharyngeal recess, or fossa of Rosenmüller, is by some regarded as a persistent par the second pharyngeal pouch, but it is probably developed as a secondary formati From the third pharyngeal pouch the thymus arises as an entodermal diverticul on either side, and from the fourth pouches small diverticula project and beco incorporated with the thymus, but in man they probably never form true thym tissue. The parathyreoids arise as diverticula from the third and fourth pouch From the fifth pouches the ultimobranchial bodies originate and are enveloped the lateral prolongations of the median thyreoid rudiment; they do not, howev form true thyreoid tissue, nor are any traces of them found in the human adult.

FIG. 118.—The head of a human embryo about twenty-nine days old. Ventral aspect. (From a model by His.)

The **nose and face.**—During the fourth week two areas of thickened ectoderm, *olfactory plates*, appear immediately under the fore-brain in the anterior wall of stomodæum, one on either side of a region termed the *frontonasal process*. the upgrowth of the surrounding parts these areas are converted into the *olfact*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

pits, which indent the frontonasal process and divide it into a *medial* and two *lateral nasal processes* (figs. 118, 119). The rounded lateral angles of the medial process are named the *globular processes* (His). From the ectodermal lining of the olfactory pits the epithelium of the nasal cavities is derived. The mesodermal plates which are represented on the surface by the globular processes are termed the *nasal laminæ*; these laminæ are at first some distance apart, but, gradually approaching, they ultimately fuse and form the nasal septum; the processes themselves meet in the middle line, and form the premaxillæ and the central part of the upper lip (fig. 122). The depressed part of the medial nasal process between the globular processes forms the lower part of the nasal septum or *columella*; while above this is seen a prominent angle, which becomes the future apex (figs. 118, 120), and still higher a flat area, the future bridge of the nose. The vomeronasal cartilage, which supports the rudimentary organ of Jacobson and is found in the nasal septum, just above the nasopalatine recess, is derived from the anterior part of the common

FIG. 119.—The head-end of a human embryo about thirty or thirty-one days old. Ventral aspect. (From a model by K. Peter.)

FIG. 120.—The same embryo as is shown in fig. 119, with the front wall of the pharynx removed.

paraseptal cartilage (p. 76). The lateral nasal process forms the ala of the nose, and from the cartilage of this process the lamina cribrosa and labyrinth of the ethmoidal bone, the inferior nasal concha, the lesser alar cartilages, and the crus laterale of the greater alar cartilage are developed. The lacrimal and nasal bones, and the frontal process of the maxilla are ossified in the membrane covering the cartilage of the lateral nasal process. The maxillary process is separated for a time from the lateral nasal process by a groove, the *naso-optic furrow*, which extends from the furrow encircling the eyeball to the olfactory pit. The maxillary processes ultimately fuse with the lateral nasal and globular processes, and form the lateral parts of the upper lip and the posterior boundaries of the nares (figs. 121, 122). From the third to the fifth month the nares are filled by masses of epithelium, on the breaking down and disappearance of which the permanent openings are produced. By the fusion of the maxillary processes with the nasal and globular processes in the roof of the stomodæum the *primitive palate* (fig. 123) is formed, and the olfactory pits extend backwards above it. The posterior end of each pit is closed by an epithelial membrane, the *bucconasal membrane*, formed by the apposition of the nasal and stomodæal epithelium. About the fifth week the bucconasal membranes rupture and the *primitive choanæ* or openings between the olfactory pits and the stomodæum are established. The floor of the nasal cavity is completed by the development of a pair

udiments of the *vomeronasal organs* of Jacobson, which open below, close to the unctions of the premaxillæ and maxillæ.*

* J. Ernest Frazer (Hunterian Lecture, *Lancet*, July 8, 1916) maintains that the increase in ize of the nasal cavities takes place in an upward and backward direction, and the septum is imply the part of the roof left undisturbed between the paired upgrowths. He also points ut that by the ninth week the primitive choanæ extend from the primitive palate to the top f the cavity of the mouth, and when the palatal folds meet they fuse with the lower two-hirds or three-fourths of the septum, while the upper one-fourth or so of the septum remains etween the upper parts of the openings which constitute the permanent choanæ.

Applied Anatomy.—Cleft palate is a common malformation. The cleft usually s posteriorly, and its most elementary form is a bifid uvula; or the cleft may extend thr the soft palate; or the posterior part of the hard palate may be involved as far forw as the incisive foramen. In the severest forms, the cleft passes between the inc bone or premaxilla and the rest of the maxilla, and extends through the alveolar pro between the lateral incisor and canine teeth. The palatine portion of the premaxilla con of a medial part corresponding to the medial incisor, and a lateral part to the lateral inc These two parts may fail to unite, and the cleft then runs between the central and la incisor teeth. The cleft may affect one or both sides; if the latter, the premaxilla frequently displaced forwards and remain united to the septum of the nose, the defici in the alveolus being complicated with a cleft in the lip (hare-lip). Where the alv is not implicated, the cleft is usually in the median line, but occasionally it is unila and in some cases bilateral. In those cases where the palatine processes fail to unite each other and with the nasal septum, the cleft of the palate is median; where one pala process unites with the nasal septum, the other failing to do so, the cleft in the pala unilateral. In some cases where the palatine processes fail to meet in the middle, the n septum may grow downwards between them and thus produce a bilateral cleft.

The **limbs.**—In the third week the limbs begin to make their appearance as s elevations or buds from a slight lateral ridge at either side of the trunk (fig. 1 Prolongations from several primitive segments extend into each bud, and ca with them the anterior divisions of the corresponding spinal nerves; the ner supplying the limbs indicate the number of primitive segments which contrib to their formation—the upper limb being derived from seven, viz. fourth cervi to second thoracic inclusive, and the lower limb from ten, viz. twelfth thoracic to fourth sacral inclusive. The axial part of the mesoderm of the limb-bud condenses and is converted into its cartilaginous skeleton, and by the ossification of this the bones of the limbs are formed. The limbs are at first directed backwards nearly parallel to the long axis of the trunk; by the sixth week their long axes are at right angles to that of the trunk, and the three chief divisions of each limb are marked off by furrows—arm, forearm, and hand in the upper limb; thigh, leg, and foot in the lower (fig. 127). The future *flexor* surface of the limb is directed ventrally; the *extensor* surface, dorsally; one border, the *pre-axial*, looks towards the cephalic end of the embryo, and the other, the *post-axial*, towards the caudal e The lateral epicondyle of the humerus, the radius, and the thumb lie along the p axial border of the upper limb; the medial epicondyle of the femur, the tibia, a the great toe along the corresponding border of the lower limb. The limbs n undergo a rotation or torsion through an angle of 90° around their long axes, rotation being effected almost entirely at the limb girdles. The rotation of upper limb is outwards and forwards; that of the lower limb is inwards and ba wards. As a consequence of this rotation the pre-axial (radial) border of the f limb is directed lateralwards, and the pre-axial (tibial) border of the hind-li medialwards; thus the flexor surface of the fore-limb is turned forwards, and t of the hind-limb backwards. The pre-axial part is derived from the ante primitive segments, the post-axial from the posterior primitive segments of limb-bud; and this explains, to a large extent, the innervation of the adult li the nerves of the more anterior segments being distributed along the pre-a (radial or tibial), and those of the more posterior segments along the post-a (ulnar or fibular) border of the limb.

Fig. 126.—A human embryo between thirty- and thirty-four days old. (His.)

The **joints.**—The mesoderm from which the different parts of the skeleton formed at first shows no differentiation into masses corresponding with the in vidual bones; thus, continuous cores of mesoderm form the axes of the limb-bu

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

nd a continuous column of mesoderm the future vertebral column. The first ndications of the differentiation of the bones and joints are circumscribed conden- ations of the mesoderm; these condensed parts become chondrified and finally ssified to form the bones of the skeleton. The intervening non-condensed portions onsist at first of undifferentiated mesoderm, which may be converted into fibrous issue as in the case of the skull bones, a synarthrodial joint being the result; or it nay become partly cartilaginous, in which case an amphiarthrodial joint is formed; r it may become looser in texture, a cavity ultimately appearing in its midst, while he cells lining the sides of this avity form a synovial stratum, nd thus a diarthrodial joint s developed; in some diarth- odial joints portions of the mesoderm persist and form arti- ular discs.

The tissue surrounding the riginal mesodermal core forms ibrous sheaths for the developing ones (perichondrium and perios- eum) which are continued be- ween the ends of the bones ver the synovial strata as the ibrous capsules of the joints. These capsules are not of niform thickness, so that in hem may be recognised specially trengthened bands which are escribed as ligaments. This, owever, is not the only method f formation of ligaments. In ome cases by modification of, r derivations from, the tendons urrounding the joint, additional igamentous bands are provided o strengthen the articulations.

FIG. 127.—A human embryo about six weeks old. (His.)

The **muscles.**—The voluntary muscles are developed from the myotomes of he primitive segments. Portions of the myotomes retain their position on the ides of the neural tube, where they may remain distinct from each other and form he short muscles of the vertebral column, or fuse with corresponding portions of eighbouring myotomes to form the Sacrospinales and their continuations. Other ortions of the myotomes extend into the trunk wall where again they may retain heir segmental condition, as in the Intercostales, or may fuse with adjacent egments to form the flat muscles of the abdominal wall. Finally, portions of the nyotomes wander into the limb-buds and there undergo fusions and alterations n form to produce the limb muscles. The original segmental character of the limb nuscles is therefore lost, but their segmental nerve supplies are retained. Some of he limb muscles expand and migrate secondarily towards the mid-dorsal line (e.g. rapezius and Latissimus dorsi) or towards the mid-ventral line (e.g. Pectoralis najor). Again, muscles may migrate in a cephalic direction (e.g. the facial muscles which are derived from the hyoid arch), or in a caudal direction (e.g. the Serratus nterior). In all cases they carry with them the segmental nerves of the myotomes rom which they are derived; one example of this will suffice, viz. the Serratus nterior, which is derived from the fifth, sixth, and seventh cervical segments as is ndicated by its nerves of supply. In man and the higher vertebrates many of the erivatives of the myotomes degenerate and are converted into aponeuroses (e.g. he galea aponeurotica, and the aponeuroses of the abdominal muscles) or ligaments e.g. the sacrotuberous ligament and the fibular collateral ligament of the knee).

The involuntary muscles are derived from the splanchnopleure mesoderm.

The **skin and its appendages.**—The epidermis, hairs, nails, sebaceous and udoriferous glands are developed from the ectoderm, the corium or true skin rom the mesoderm. The ectoderm at first consists of a single stratum of cells, ut by the fifth week two strata can be recognised, a superficial, named the *pitrichium*, consisting of flat nucleated cells readily, and a deep,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

named the *stratum germinativum*, consisting at first of cubical, but later columnar, cells. By multiplication and differentiation of the cells of the stratum germinativum the different layers of the epidermis are developed. Towards the end of the third month the mesoderm condenses to form the corium, and at about the same time the subcutaneous areolar tissue is differentiated; in the fifth month the dermal papillæ begin to make their appearance. A considerable desquamation of the epidermis takes place; this desquamated epidermis, mixed with sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of fœtal life.

FIG. 128.—Successive stages in the development of a hair.

The *hairs* (fig. 128) originate as thickenings of the epidermis which grow obliquely downwards as solid buds into the corium, each bud consisting of an outer stratum of columnar cells and a core of polygonal cells. The deep end of each bud expands to form the hair-bulb, which is moulded over a papilla of condensed mesoderm. The cells of the hair-bulb proliferate and form a cone of cells, from which the scapus or shaft of the hair and its internal sheath are developed; the hairs gradually lengthen by growth at the hair-bulb, and ultimately project on the surface.

The *sebaceous glands* originate as lateral outgrowths from the sides of the hair-bulbs and, pushing their way into the mesoderm, divide into three or four oval or flask-shaped alveoli, the lining cells of which are derived from the stratum germinativum.

The rudiments of the *sudoriferous or sweat glands* make their appearance on the palms of the hands and soles of the feet in the fourth month, and closely resemble the rudiments of the hairs, each beginning as a solid downgrowth of the ectoderm. The ectodermal downgrowth lengthens, and its deeper part coils on itself and forms the body of the gland. A lumen is developed in the downgrowth about the seventh month of fœtal life, and opens on the surface by a duct which is lined with two layers of cells. In the secreting part of the gland the outer layer of cells is modified to form a stratum of smooth muscle-fibres which lies between the epithelium of the gland and the basement-membrane. Many sudoriferous glands arise as ectodermal downgrowths from the superficial portions of the hair-follicles, and later acquire independent openings on the surface of the skin.

The *mammary gland* may be looked upon as a collection of greatly modified sudoriferous glands; the epithelial lining of its ducts and alveoli is derived from the ectoderm, its supporting connective tissue from the mesoderm. On either side of the ventral surface of young embryos a thickened band of ectoderm, termed the *milk-ridge*, extends obliquely from the axilla to the inguinal region, and in some of the lower mammals mammæ are developed at intervals along this ridge. In man only one mamma, as a rule, is developed on either side of the middle line, but supernumerary glands or nipples are sometimes found above or below the fully developed gland.

The rudiment of the mamma appears as a thickening and subsequent downgrowth of the ectoderm; from this downgrowth fifteen or twenty solid cords branch off, each cord representing a future lactiferous tubule and lobe of the gland.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

eep ends of the cords subdivide in the mesoderm and form the alveoli of the land. The region where the ectodermal thickening occurred is subsequently ised to form the nipple, and about the time of birth the tubules and alveoli ecome canalised. At the age of puberty, and in a greater degree towards the end f pregnancy, a marked enlargement of the gland, and a development of additional bules and alveoli, take place.*

The rudiments of the *nails* can be seen in embryos of about 4·5 cm. in length, nd appear as *primary nail-fields* of ectoderm on the dorsal surfaces of the terminal halanges of the digits. At the proximal end and sides of each nail-field the epiermis is invaginated to form the nail-folds, while the distal end, which will ltimately form the free end of the nail, is bounded by a shallow groove. The nail developed from the posterior nail-fold and consists of modified stratum lucidum. he stratum corneum covers the nail and forms the *eponychium*; this disappears om the surface of the nail, with the exception of a narrow fold which overlaps e proximal part of the lunule of the nail.

HE DEVELOPMENT OF THE NERVOUS SYSTEM AND SENSE-ORGANS

The nervous system is derived from the ectoderm and first appears as the neural oove on the dorsal aspect of the embryo (fig. 80). By the elevation and ultimate sion of the neural folds, the groove is converted into the neural tube (fig. 82). he anterior end of the tube expands to form the three primary brain-vesicles; e cavity of the tube is subsequently modified to form the ventricular cavities of he brain and the central canal of the medulla spinalis; from the wall the nervous lements and the neuroglia of the brain and medulla spinalis are developed.

The **medulla spinalis.**—At first the wall of the neural tube is composed of a ngle layer of columnar ectodermal cells. The lateral parts of the wall soon thicken, hile the dorsal and ventral parts remain thin, and are named the *roof-* and *floorlates* (figs. 129, 131). A transverse section of the tube at this stage presents an val outline and a slit-like lumen. The cells which constitute the wall of the tube roliferate rapidly, lose their cell-boundaries and form a syncytium consisting at rst of dense protoplasm with closely packed nuclei, but later opening out and orming a loose meshwork with the strands radiating from the central canal. hree layers of this syncytium may be defined—an internal or ependymal, an ntermediate or mantle, and an external or marginal (fig. 129). The *ependymal layer* ultimately converted into the ependyma of the central canal; the processes of s cells pass outwards towards the periphery of the medulla spinalis. The *marginal yer* is devoid of nuclei, and later forms the supporting framework for the white nniculi of the medulla spinalis. The *mantle layer* represents the future grey columns f the medulla spinalis; its cells are differentiated into two sets, viz. (*a*) *spongioasts* or young neuroglia-cells, and (*b*) *neuroblasts* or young nerve-cells (fig. 130). he spongioblasts are connected to another one by filaments of the syncytium; these, fibrils are developed, so that as the neuroglia cells become defined they khibit their characteristic mature appearance with multiple processes proceeding om each cell. The neuroblasts are large, round or oval, and first make their ppearance between the ependymal cells on the sides of the central canal. They ncrease rapidly in number, so that by the fourth week they form an almost conuous layer on either side of the central canal. No neuroblasts are found in he roof- or floor-plates; the roof-plate retains, in certain regions of the brain, its pithelial character; elsewhere, its cells become spongioblasts. The neuroblasts r young nerve-cells migrate from the sides of the central canal into the mantle yer, and at the same time become pear-shaped; the tapering part of the cell ndergoes still further elongation, and forms the axis-cylinder of the cell.

The lateral walls of the medulla spinalis increase in thickness, and the central nal widens out near its dorsal extremity, and assumes a somewhat lozenge-shaped ppearance. The widest part of the canal subdivides the lateral wall of the neural be into a *dorsal or alar*, and a *ventral or basal lamina* (fig. 131), a subdivision hich extends into the brain. The dorsal part of the canal is reduced to a mere t which is subsequently obliterated by the approximation and fusion of its walls; e ventral part persists as the central canal of the adult medulla spinalis. The

caudal end of the canal exhibits a conical expansion which is known as the *terminal ventricle*.

The ventral part of the mantle layer increases in thickness, and on cross-section appears as a triangular patch between the marginal and ependymal layers. This thickening is the rudiment of the anterior column of grey substance, and contains many motor neuroblasts, the axis-cylinders of which pass out through the marginal layer and form the anterior roots of the spinal nerves (fig. 129). Dart and Shellshear * are of opinion that the motor neuroblasts originate in the myotomes, and migrate into the wall of the neural tube. The thickening of the mantle layer gradually extends in a dorsal direction, and forms the posterior column of grey substance. In the thoracic and upper lumbar regions a lateral or intermediate column of grey substance is differentiated. The axons of the cells of this column form the splanchnic efferent nerves; they emerge in the anterior nerve-roots, and pass through the white rami communicantes to the ganglia of the sympathetic

FIG. 129.—A transverse section through the medulla spinalis of a human embryo four weeks old. (His.)

trunk. The axons of many of the neuroblasts in the alar lamina run forward, cross in the floor-plate to the opposite side of the medulla spinalis, and form the rudiment of the anterior white commissure.

About the end of the fourth week nerve-fibres appear in the marginal layer. The first to develop are the short intersegmental fibres from the neuroblasts in the mantle zone, and the fibres of the posterior roots of the spinal nerves which pass into the medulla spinalis from the cells of the spinal ganglia. By the sixth week the fibres of the posterior roots of the spinal nerves form a well-defined *oval bundle* in the peripheral part of the alar lamina; this bundle increases in size, and spreads towards the middle line forms the rudiment of the posterior funiculus. The long intersegmental fibres begin to appear about the third month, and the cerebrospinal fibres about the fifth month. All nerve-fibres are at first destitute of medullary sheaths, and different groups of fibres receive their sheaths at different times, e.g. the anterior and posterior nerve-roots are medullated about the fifth month, the cerebrospinal fibres after the ninth month.

By the growth of the anterior columns of grey substance, and by the increase in size of the anterior funiculi, an anterior furrow is formed between the lateral halves of the medulla spinalis; this gradually deepens to form the anterior median fissure (fig. 131, B). The mode of formation of the posterior septum is somewhat uncertain. It is probably produced by the growing together of the walls of the posterior part of the central canal and by the development from its ependyma

ells of a septum of fibrillated tissue which separates the future funiculi graciles. he cervical and lumbar enlargements appear simultaneously with the development f the limb-buds.

FIG. 130.—A transverse section through the medulla spinalis of a human embryo at the beginning of the fourth week. (After His.) The left edge of the figure corresponds to the lining of the central canal.

In early fœtal life the medulla spinalis occupies the entire length of the vertebral anal, and the spinal nerves pass outwards at right angles. When the embryo has ttained a length of 30 mm. the vertebral column begins to grow farther caudalvards than the medulla spinalis, and the latter gradually assumes a higher position within the vertebral canal, the principal part of this upward migration occurring luring the first half of fœtal life. By the twenty-fifth week of fœtal life the terminal entricle of the medulla spinalis (p. 86) has ascended from the level of the second

FIG. 131.—Transverse sections through the medullæ spinales of human embryos. A, about four and a half weeks old. B, about three months old. (His.)

occygeal vertebra to that of the third lumbar vertebra, or a distance of nine gments, and there remain but two segments before the adult position is reached treeter *). A delicate filament, the *filum terminale*, extends from the lower end

of the medulla spinalis as far as the first piece of the coccyx, and represents part of the fœtal medulla spinalis which is caudal to the second coccygeal segm and has become converted into a fibrous strand. This strand, like the sacral n roots, elongates in adaptation to the ascending displacement of the medulla spi

The spinal nerves.—Each spinal nerve is attached to the medulla spinal an anterior and a posterior root.

The fibres of the anterior or motor roots are formed by the axons of the n blasts which lie in the ventral part of the mantle layer; these axons grow through the overlying marginal layer into the myotomes of the primitive segm and are ultimately aggregated to form the anterior nerve-roots (fig. 129).

The fibres of the posterior roots are developed from the cells of the spinal ga Before the neural groove is closed to form the neural tube a ridge of ectode cells, the *ganglion-ridge* or *neural crest* (fig. 132), appears along the prominent ma of each neural fold. When the folds meet in the middle line the two ganglion-ri fuse and form a wedge-shaped area along the line of closure of the tube. cells of this area proliferate rapidly opposite the primitive segments to form a s of oval-shaped masses which their connexions with the ne tube and then migrate for a sh distance in a lateral and ven direction. From the ventral p of each mass a small portion detached to form a sympath ganglion, while the remainde converted into a spinal gangl These spinal ganglia are arran symmetrically on the two side the neural tube and, except in region of the tail, are equal number to the primitive segme The cells of the ganglia, like cells of the mantle layer, are two kinds, viz. spongioblasts neuroblasts. The spongioblast velop into the neuroglial cells of ganglia. The neuroblasts, at round or oval in shape, soon ass the form of spindles the extrem of which gradually elongate central and peripheral proces The central processes grow med wards and, becoming connected with the neural tube, constitute the fibres of posterior nerve-roots, while the peripheral processes grow lateralwards to mi with the fibres of the anterior root in the spinal nerve. As development proc the original bipolar form of the cells changes; the two processes bec approximated until they ultimately arise from a single stem in a T-shaped man The bipolar form is retained in the retina and in the ganglia of the acoustic ne Some recent observers hold, however, that the T-form is derived from the bra ing of a single process which grows out from the cell.

Fig. 132. Two stages in the development of the neural crest in the human embryo. (Lenhossék.)

Many embryologists maintain (1) that each motor nerve-cell gives origin single motor nerve-fibre which later becomes connected to its own special myot and (2) that each sensory nerve-cell gives origin to two processes, a central w grows into the medulla spinalis or into the brain, and a peripheral which p outwards to unite with the sense-organ supplied by the nerve. It is, howe probable that the myotomes and the peripheral sense-organs are from the connected with the central nervous system, and that this connexion is never lost. *Lepidosiren paradoxa*, Graham Kerr * has traced back the development of the m nerve-trunk to a period in which it is represented by a bridge of soft granular p plasm connecting the medulla spinalis and myotome at a stage when these struct are in close apposition. As the myotome is pushed outwards it remains conne with the medulla spinalis by the ever-lengthening strand of nerve, which soon lose granular protoplasmic character and assumes a fibrillated appearance. A sin

ndition probably exists regarding the development of sensory nerve-fibres, for meron and Milligan * have shown that in early embryonic life the cell-elements of e sense-epithelium of the auditory vesicle are connected with those of the hind-rain by a continuous tract of nucleated protoplasm (syncytium) which is never

FIG. 133.—A human embryo 10·2 mm. long, showing the peripheral nerves. (After a reconstruction by His.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

The abducent nerve is not labelled, but is seen passing forwards to the eye under the mandibular and maxillary nerves.

vered. This syncytium, at first undifferentiated, becomes fibrillated longitudinally form a continuous tract of nerve-fibres (the future auditory nerve) uniting the nse-epithelium of the auditory organ with the hind-brain.

The anterior and posterior nerve-roots join immediately beyond the spinal nglion to form the *spinal nerve* (fig. 133), which then divides into anterior, posterior, d visceral divisions. The anterior and posterior divisions proceed directly to their eas of distribution without further association with ganglion-cells. The visceral

divisions are distributed to the thoracic, abdominal and tripelvic viscera, to which they pass through the sympathetic trunk, and many of the fibres of divisions form arborisations around the ganglion-cells of this trunk. Vi divisions are not given off from all the spinal nerves; they form two groups (*a*) *thoracicolumbar*, from the thoracic and the first and second lumbar ne and (*b*) *sacral*, from the second, third and fourth sacral nerves.

The **brain** is developed from the cephalic end of the neural tube, which early period expands into the three primary cerebral vesicles (fig. 81). The marked off from each other by constrictions, and are named the *rhombencep* or *hind-brain*, the *mesencephalon* or *mid-brain*, and the *prosencephalon* or *fore-br* the first being continuous with the medulla spinalis. As the result of the un growth of its different parts three flexures appear in the brain; two of these fle are concave ventrally and are associated with corresponding flexures of the The first appears in the region of the mid-brain, and is named the *ventral ce flexure* (figs. 134, 139); the fore-brain bends in a ventral direction around the an end of the notochord and fore-gut until its floor lies almost parallel with th

Fig. 134.—A diagram to illustrate the alar and basal laminæ of the brain vesicles. (His.)

Fig. 135.—A transverse section through medulla oblongata of a human embryo. × (From Kollmann's Entwickelungsgeschic

the hind-brain. The mid-brain is for a time the most prominent part of the b since its dorsal surface corresponds with the convexity of the flexure. The sec bend appears at the junction of the hind-brain and medulla spinalis, and is ter the *cervical flexure* (fig. 138). It increases from the third to the end of the week, when the hind-brain forms nearly a right angle with the medulla spin after the fifth week erection of the head takes place and the cervical flexure dimin and disappears. The third bend is named the *pontine flexure* (fig. 140), bec it is found in the region of the future pons (Varolii). It differs from the two in that (*a*) its convexity is forwards, and (*b*) it does not affect the head.

The lateral walls of the brain-tube, like those of the medulla spinalis, are div by internal furrows into dorsal or alar and ventral or basal laminæ (figs. 134, 1

The **rhombencephalon** or **hind-brain**.—The cavity of the hind-brain bec the fourth ventricle. By the time the ventral cephalic flexure appears the h brain exceeds in length the combined lengths of the other two brain vesi Anteriorly it exhibits a constriction, the *isthmus rhombencephali* (fig. 134, Isthm which is best seen when the brain is viewed from the dorsal aspect. From isthmus the brachia conjunctiva of the cerebellum and the anterior medu velum are formed. The rest of the hind-brain consists of two parts, an up the *metencephalon*, and a lower, the *myelencephalon*. The cerebellum is develo by a thickening of the roof, and the pons by a thickening of the floor and la walls of the metencephalon. The floor and lateral walls of the myelencep

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

thickened to form the medulla oblongata; its roof remains thin, and, retaining a great extent its epithelial nature, is expanded in a lateral direction. Later, by growth and backward extension of the cerebellum, the roof is folded inwards wards the cavity of the fourth ventricle; it assists in completing the dorsal ll of this cavity, and is also invaginated to form the ependymal covering of chorioid plexuses of the ventricle. Above it is continuous with the posterior dullary velum; below, with the obex and ligulæ.

The development of the *medulla oblongata*, though resembling that of the medulla nalis, exhibits one or two interesting modifications. At an early stage the elencephalon consists of two lateral walls, connected across the middle line floor- and roof-plates (figs. 135, 136). Each lateral wall consists of an alar d a basal lamina, separated by an internal furrow, the remains of which are resented in the adult brain by the sulcus limitans of the rhomboid fossa. e contained cavity is more or less triangular in section, the base being formed the thin and greatly expanded roof-plate, the upper part of which ultimately ms the posterior medullary velum. Pear-shaped neuroblasts are developed in

FIG. 136.—A transverse section through the medulla oblongata of a human embryo. (After His.)

e alar and basal laminæ, and their narrow stalks are elongated to form the axis-linders of the nerve-fibres. Opposite the furrow or boundary between the alar d basal laminæ a bundle of nerve-fibres attaches itself to the outer surface of alar lamina. This is named the *tractus solitarius* (fig. 136), and is formed by sensory fibres of the glossopharyngeal and vagus nerves. It is the homologue the *oval bundle* seen in the medulla spinalis (p. 86), and, like it, is developed an ingrowth of fibres from the ganglia of the neural crest. At first it is applied the outer surface of the alar lamina, but is soon buried by the growth over it the neighbouring parts. By the fifth week the dorsal part of the alar lamina nds in a lateral direction along its entire length to form what is termed the *mbic lip* (figs. 136, 140). Within a few days this lip adheres to, and unites with, e outer surface of the main part of the alar lamina, and so covers in the tractus itarius and also the spinal root of the trigeminal nerve.

Neuroblasts accumulate in the mantle layer; those in the basal lamina corre-ond with the cells in the anterior grey column of the medulla spinalis, and, like em, give origin to motor nerve-fibres; in the medulla oblongata the neuroblasts e arranged in groups or nuclei, instead of forming a continuous column as in the dulla spinalis. From the alar lamina and its rhombic lip, neuroblasts migrate o the basal lamina, where some are aggregated to form the olivary nuclei, while ny send their axis-cylinders through the floor-plate to the opposite side, and s constitute the rudiment of the raphe of the medulla oblongata. By means of s thickening of the ventral portion, the motor nuclei are buried deeply in the erior, and in the adult are found close to the rhomboid fossa. This is still

further accentuated: (a) by the development of the pyramids of the m oblongata, which are formed about the fourth month by the downgrowth cerebrospinal fasciculi; and the fibres which pass to and the cerebellum.

Fig. 137.—The hind-brain of a human embryo about three months old. Viewed from behind and partly from the right side. (From a model by His.)

The *pons* is developed fr ventrolateral wall of the m cephalon by a process simi that which has been describ the ventrolateral wall of the m oblongata.

The *cerebellum* is develop the roof of the anterior part hind-brain (figs. 137 to 142), alar laminæ of this part incre thickness and form two lateral which fuse in the middle lin produce a thick lamina which the upper part of the cavity hind-brain vesicle; this lamina stitutes the rudiment of the bellum, the outer surface of is originally smooth and co The flocculus and nodule are veloped from the rhombic lip, are recognisable as separate po before any of the other cere lobules. The fissures of the cerebellum appear first in the vermis and floc region, and traces of them are found during the third month; the fissur the cerebellar hemispheres do not appear till the fifth month. The primitive fissures are not developed in the order of their relative size in the adult—thus the horizontal sulcus at the fifth month is merely a shallow groove. The more important of the early fissures are: (a) the *fissura prima* between the developing culmen and clivus, and (b) the *fissura secunda* between the future pyramid and uvula. The groove produced by the bending over of the rhombic lip is here known as the *floccular fissure*; when the two lateral walls fuse, the right and left floccular fissures join in the middle line, and their central part becomes the *postnodular fissure*.

Fig. 138.—The brain of a human embryo four and a half weeks old. Right aspect. (From a model by His.)

On the ventricular surface of the cerebellar lamina a transverse furrow, the *incisura fastigii*, appears and then deepens to form the tent-like recess of the roof of the fourth ventricle. The rudiment of the cerebellum at first projects in a dorsal direction; but, by the backward growth of the cerebrum, it is folded downwards, and somewhat flattened, and the thin roof-plate of the fourth ventricle, originally continuous with the posterior border of the cerebellum, is projected inwards tow the cavity of the ventricle.

After the seventh month of fœtal life the cerebellum increases very rapidly in e.*

The **mesencephalon** or **mid-brain** (figs. 138 to 142) exists for a time as a thin-lled cavity of some size, and is separated by slight constrictions from the isthmus mbencephali and the fore-brain. Its cavity becomes relatively reduced in meter, and forms the cerebral aqueduct of the adult brain. The basal laminæ the mid-brain increase in thickness to form the cerebral peduncles, which are first of small size, but rapidly enlarge after the fourth month. Many of the uroblasts of these laminæ are uped in relation to the sides and or of the cerebral aqueduct, and nstitute the nuclei of the oculo-tor and trochlear nerves, and of mesencephalic root of the tri-minal nerve; others are aggre-ed to form the red nuclei. By a ilar thickening process the alar inæ are developed into the adrigeminal lamina. The dorsal t of the wall expands, and for ime presents an internal median row and a corresponding external ge; these, however, disappear, the latter is replaced by a ove. Subsequently two oblique rows extend medialwards and ckwards, and the thickened nina is thus subdivided into the perior and inferior colliculi.

Fig. 139.—The brain of a human embryo, about four and a half weeks old. (From a model by His.)

The **prosencephalon** or **fore-ain.**—A transverse section through e early fore-brain shows the me parts as are displayed in nilar sections of the medulla inalis and medulla oblongata, . a pair of thick lateral walls nnected by thin floor- and roof-ates. Moreover, each lateral wall divided into a dorsal or alar and entral or basal lamina separated ernally by a furrow termed the *cus of Monro.* This sulcus ends anteriorly at the medial end of the optic stalk, l in the adult brain is retained as a slight groove extending backwards from the erventricular foramen to the cerebral aqueduct.

At a very early period—in some animals before the closure of the cranial part of neural tube—two lateral diverticula, the *optic vesicles*, appear, one on either side the fore-brain; for a time they communicate with the cavity of the fore-brain by atively wide openings. The distal parts of the vesicles expand, while the proximal rts are reduced to tubular stalks, the *optic stalks*; their further development iven on pp. 101 to 104. The fore-brain then grows forwards, and from the alar inæ of this front portion the cerebral hemispheres originate as diverticula which idly expand to form two large pouches, one on either side. The cavities of se diverticula are the rudiments of the lateral ventricles; they communicate h the median part of the fore-brain cavity by relatively wide openings which imately form the interventricular foramen (foramen of Monro). The median tion of the wall of the fore-brain vesicle consists of a thin lamina, the *lamina minalis* (figs. 142, 145), which stretches from the interventricular foramen to recess at the base of the optic stalk. The anterior part of the fore-brain, includ-the rudiments of the cerebral hemispheres, is named the *telencephalon*, and the terior portion the *diencephalon*; both contribute to the formation of the third tricle.

The *diencephalon*.—From the alar lamina of the diencephalon, the thal metathalamus, and epithalamus are developed. The *thalamus* (figs. 138 t arises as a thickening which involves the anterior two-thirds of the alar lamina two thalami are visible, for a time, on the surface of the brain, but are subseq hidden by the cerebral hemispheres which grow backwards over them. The t extend medialwards and gradually narrow the interval between them into a s cavity which forms the greater part of the third ventricle; their medial su adhere, in part, to each other, and the *intermediate mass* of the ventricle is dev across the area of contact. The *metathalamus* comprises the medial and geniculate bodies which originate as slight outward bulgings of the alar la In the adult the lateral geniculate body appears as an eminence on the latera of the posterior end of the thalamus, while the medial lies under cover of the pu

FIG. 140.—The brain of a human embryo, about five weeks old. Right later aspect; the roof of the hind-brain has been removed. (From a model b His.)

of the thalamus. The *epithalamus* includes the pineal body, the posterior missure, and the trigonum habenulæ. The pineal body arises as a bilateral eva tion of the roof-plate immediately in front of the mid-brain; only the left po of this evagination persists in vertebrates, and it becomes solid with the exce of its proximal part, which forms the recessus pinealis. The pineal body co essentially of (*a*) a distal part representing a rudimentary eye, and (*b*) a pro part which is glandular in nature; only this latter portion is represented in The posterior commissure is formed by the ingrowth of fibres into the depr behind and below the pineal evagination, and the trigonum habenulæ is deve in front of the pineal recess.

From the basal laminæ of the diencephalon the *pars mamillaris hypoth* is developed; this comprises the corpora mamillaria and the posterior part tuber cinereum. The corpora mamillaria arise as a single thickening, whi divided by a median furrow during the third month.

The roof-plate of the diencephalon, in front of the pineal body, remains thi epithelial in character, and is subsequently invaginated by the chorioid ple of the third ventricle.

The *telencephalon* consists of a median portion and two lateral divert The median portion forms the anterior part of the cavity of the third vent and is closed below and in front by the lamina terminalis. The lateral divert consist of outward pouchings of the alar lamina; the cavities represent the f

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ral ventricles, and their walls the nervous matter of the cerebral hemispheres. roof-plate of the telencephalon remains thin, and is continuous in front with lamina terminalis, and behind with the roof-plate of the diencephalon. In basal laminæ and floor-plate the *pars optica hypothalami* is developed; this prises the anterior part of the tuber cinereum, the infundibulum and posterior e of the hypophysis, and the optic chiasma. The anterior part of the tuber ereum is derived from the posterior part of the floor of the telencephalon; the undibulum and posterior lobe of the hypophysis arise as a downward diverticulum m the floor. The most dependent part of the diverticulum becomes solid and ms the posterior lobe of the hypophysis; the anterior lobe of the hypophysis leveloped from a diverticulum of the ectodermal lining of the stomodæum (p. 135). e optic chiasma is formed by the meeting and partial decussation of the optic ves, which subsequently grow backwards as the optic tracts and end in the ncephalon.

FIG. 141.—The brain of a human embryo about five weeks old. Medial aspect of right half. The roof of the hind-brain has been removed. (From a model by His.)

The *cerebral hemispheres* arise as diverticula of the alar laminæ of the telen- halon (figs. 138 to 142); they increase rapidly in size and ultimately overlap structures developed from the mid- and hind-brains. This great expansion he hemispheres is a characteristic feature of the brains of mammals, and attains maximum development in the brain of man. G. Elliot Smith divides each ebral hemisphere into three fundamental parts, viz. the rhinencephalon, the pus striatum, and the neopallium.

The *rhinencephalon* (figs. 140 to 143) represents the oldest part of the telen- halon, and forms almost the whole of the hemisphere in fishes, amphibians, and tiles. In man it is feebly developed in comparison with the rest of the hemi- ere, and comprises the following parts, viz. the olfactory lobe (consisting of the ctory tract and bulb, and the trigonum olfactorium), the anterior perforated stance, the septum pellucidum, the subcallosal, supracallosal, and dentate gyri, fornix, the hippocampus, and the uncus. The rhinencephalon appears as a gitudinal elevation, with a corresponding internal groove, on the under surface he hemisphere close to the lamina terminalis; it is separated from the lateral ace of the hemisphere by a furrow, the *external rhinal fissure*, and is continuous nd with that part of the hemisphere which will ultimately form the anterior end he temporal lobe. The elevation is divided by a groove into an anterior and sterior part. The anterior grows forward as a hollow stalk, the lumen of which

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is continuous with the anterior part of the lateral ventricle. During the month the stalk becomes solid and forms the rudiment of the olfactory bulb tract; a strand of gelatinous tissue in the interior of the bulb indicates the p of the original cavity. From the posterior part the anterior perforated sub and the pyriform lobe are developed; at the beginning of the fourth mon latter forms a curved elevation continuous behind with the medial surface temporal lobe, and consisting, from before backwards, of the gyrus olfa lateralis, gyrus ambiens, and gyrus semilunaris, parts which in the adult are represented by the lateral root of the olfactory tract and the uncus position and connexions of the remaining portions of the rhinencephalon are de with the anatomy of the brain.

The *corpus striatum* (figs. 139, 141) appears in the fourth week as a tria thickening of the floor of the telencephalon between the optic recess and the

FIG. 142.—The brain of a human embryo, about three months old. Medi aspect of right half. (From a model by His.)

ventricular foramen, and continuous behind with the thalamic part of the cephalon. It increases in size, and by the second month forms a swelling i floor of the future lateral ventricle; this swelling reaches as far as the pos end of the primitive hemisphere, and when this part of the hemisphere backwards and downwards to form the temporal lobe, the posterior part corpus striatum is carried into the roof of the inferior horn of the ventricle, it is seen as the tail of the caudate nucleus in the adult brain. During the and fifth months the corpus striatum becomes incompletely subdivided b fibres of the internal capsule into two masses, an inner, the caudate nucleu an outer, the lentiform nucleus. In front, the corpus striatum is continuous the anterior perforated substance; laterally it is confluent for a time with portion of the wall of the vesicle which is developed into the insula, but this tinuity is subsequently interrupted by the fibres of the external capsule.

The *neopallium* (fig. 144) forms the remaining, and by far the greater of the cerebral hemisphere. It consists, at an early stage, of a relatively more or less hemispherical cavity—the primitive lateral ventricle—enclos a thin wall from which the cortex of the hemisphere is developed. The expands in all directions, but more especially upwards and backwards, so th the third month the hemispheres cover the diencephalon, by the sixth they o the mid-brain, and by the eighth the hind-brain.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

The lamina terminalis unites the two hemispheres but does not share in their pansion, and thus the hemispheres are separated by a cleft, the forerunner of e longitudinal fissure, and this cleft is occupied by a septum of mesodermal tissue ich constitutes the primitive falx cerebri. Coincidently with the expansion of e vesicle, its cavity is drawn out into three prolongations which represent the ns of the future lateral ventricle; the hinder end of the vesicle is carried down- rds and forwards, and forms the inferior horn; the posterior horn is produced mewhat later, in association with the backward growth of the occipital lobe of the misphere. The roof-plate of the primitive fore-brain remains thin and of an ithelial character; it is invaginated into the lateral ventricle along the medial ll of the hemisphere. This invagination constitutes the chorioidal fissure, and tends from the interventricular foramen to the posterior end of the vesicle. esodermal tissue, continuous with that of the pia mater, and carrying blood-vessels th it, spreads between the two layers of the invaginated fold and forms the

FIG. 143.—The brain of an embryo at the beginning of the fourth month. Inferior aspect. (Kollmann.)

diment of the tela chorioidea; the margins of the tela become highly vascular and rm the chorioid plexuses which for some months almost completely fill the ntricular cavities; the tela at the same time invaginates the epithelial roof of e diencephalon, and there forms the chorioid plexuses of the third ventricle. By e downward and forward growth of the posterior end of the vesicle to form the mporal lobe the chorioidal fissure finally reaches from the interventricular foramen the extremity of the inferior horn of the ventricle.

Parallel with but above and in front of the chorioidal fissure the medial wall of e cerebral vesicle becomes folded and gives rise to a shallow fissure, the *hippo-mpal fissure*, on the medial surface, and to a corresponding bulging, the *hippo-mpus*, on the medial wall of the ventricular cavity.* The grey or ganglionic vering of the wall of the vesicle ends at the inferior margin of the fissure in a ickened edge; beneath this the marginal or reticular layer (future white sub-ance) is exposed, and its lower thinned edge is continuous with the epithelial vagination covering the chorioid plexus (fig. 144). As a result of the later wnward and forward growth of the temporal lobe the hippocampal fissure and e parts associated with it extend from the interventricular foramen to the end the inferior horn of the ventricle. The thickened edge of grey substance comes the gyrus dentatus, the fasciola cinerea and the supra- and sub-callosal ri, while the free edge of the white substance forms the fimbria hippocampi and e body and crus of the fornix. The corpus callosum is developed within the

arch of the hippocampal fissure, and the upper part of the fissure forms, in adult brain, the callosal fissure on the medial surface of the hemisphere.

FIG. 144.—A coronal section through the brain to show the relations of the neopallium. Diagrammatic. (After His.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

Cs. Corpus striatum. Th. Thalamus.

The commissures (fig. 145).—The development of the posterior commis has already been referred to (p. 94). The great commissures of the hemispheres, the corpus callosum, the fornix, and the anterior commissure, arise from the lam

FIG. 145.—The brain of a human embryo, four months old. Medial aspect of left half. (Marchand.)

terminalis. About the fourth month a small thickening appears in this lam immediately in front of the interventricular foramen. The lower part of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ickening is soon separated, and nerve-fibres appear in it to form the anterior mmissure. The upper part continues to grow with the hemispheres, and is vaded by two sets of fibres. Transverse fibres, extending between the hemiheres, pass into its dorsal part, which is now differentiated as the corpus callosum. to the ventral part longitudinal fibres from the hippocampus pass to the lamina rminalis, and through that structure to the corpora mamillaria; these fibres nstitute the fornix. The *paraterminal bodies*, or portions of the rhinencephalon mediately in front of the lamina terminalis, are stretched to form the subcallosal rus and the laminæ of the septum pellucidum.

The *fissures or sulci*.—Until the fifth month the surface of the cerebral hemiere is almost smooth. Between the sixth and seventh months the cortex inses rapidly in volume and becomes folded, and the surface is thus raised into a mber of elevations or convolutions, separated by fissures or sulci; the chief of se are well developed by the seventh month. The *lateral cerebral, or Sylvian, sure* differs from the others in its mode of development. About the third month depression, the *Sylvian fossa*, appears on the lateral surface of the hemisphere 146); this fossa corresponds with the position of the corpus striatum, and its

FIG. 146.—The right cerebral hemisphere of a human embryo, about five months old. Lateral aspect.

oor is moulded to form the cortex of the insula. The intimate connexion which xists between the deep surface of the cortex of the insula and the corpus striatum revents the insular part of the hemisphere wall from expanding at the same rate s the portions which surround it, with the result that the latter grow over and cover he insula, and constitute the temporal, parietal, frontal, and orbital opercula of he adult brain. The frontal and orbital opercula are the last to form, but by the nd of the first year after birth the insula is completely submerged by the approximation of the opercula. The fissures separating the opposed margins of the opercula onstitute the composite lateral cerebral fissure.

If a section across the wall of the hemisphere about the sixth week be examined icroscopically it is seen to consist of a thin marginal or reticular layer, a thick pendymal layer, and a thin intervening mantle layer. Neuroblasts from the pendymal and mantle layers migrate into the deep part of the marginal layer and orm the cells of the cerebral cortex. By the sixth month the middle cell-lamina as attained one-half, and the inner cell-lamina three-fourths of their adult thickess; the outer cell-lamina is the last to develop and its thickness varies with the tellectual capacity of the individual. The nerve-fibres which form the underlying hite substance of the hemispheres consist at first of outgrowths from the cells of he corpora striata and thalami; the fibres from the cells of the cortex are added ter. Medullation of these fibres begins about the time of birth and continues ntil puberty.

A summary of the parts derived from the cerebral vesicles is given in the foll table :—

Rhombencephalon or hind-brain	1. Myelencephalon	Medulla oblongata. Lower part of fourth ventric
	2. Metencephalon	Pons. Cerebellum. Intermediate part of fourth ventricle.
	3. Isthmus rhombencephali	Anterior medullary velum. Brachia conjunctiva cerebell Upper part of fourth ventric
Mesencephalon or mid-brain . . .		Cerebral peduncles. Lamina quadrigemina. Cerebral aqueduct.
Prosencephalon or fore-brain	1. Diencephalon	Thalamus. Metathalamus. Epithalamus. Pars mamillaris hypothalami Posterior part of third ventricle.
	2. Telencephalon	Anterior part of third ventricle. Pars optica hypothalami. Cerebral hemispheres. Lateral ventricles. Interventricular foramen.

The **cerebral nerves.**—With the exception of the olfactory, optic, and acc nerves, which will be specially considered, the cerebral nerves are developed similar manner to the spinal nerves (p. 88). The sensory or afferent fibres o trigeminal, facial, glossopharyngeal and vagus nerves are partly derived from cells of the ganglion-rudiments of the neural crest and partly from the cel certain thickened patches of the ectoderm (*placodes*), which are developed a upper ends of the branchial grooves. The central processes of these cells form roots of the nerves, the peripheral processes their fibres of distribution (fig. It has been seen, in considering the development of the medulla oblongata (p. that the *tractus solitarius* (fig. 148), derived from the ingrowing fibres from cells of the ganglion-rudiments of the glossopharyngeal and vagus nerve the homologue of the *oval bundle* in the medulla spinalis which has its origin in posterior nerve-roots. The motor nerves arise from the neuroblasts situated in basal laminæ of the mid- and hind-brain. While, however, the spinal motor ne roots arise in one series from the basal lamina, the cerebral motor nerves grouped into two sets, according as they spring from the medial or lateral p of the basal lamina. To the former set belong the oculomotor, trochlear, abduc and hypoglossal nerves; to the latter, the accessory nerve, and the motor f of the trigeminal, facial, glossopharyngeal, and vagus nerves (figs. 147, 148).

The **sympathetic system.**—The ganglion-cells of the *sympathetic system* derived from the segmented masses of the cells of the neural crests, which mig along the sides of the neural tube to form the spinal ganglia; certain cells de themselves from the ventral margins of these masses and move towards the s of the aorta, where some of them are grouped to form the ganglia of the sym thetic trunks, while others undergo a further migration and form the gangli the prevertebral and visceral plexuses. The ciliary, sphenopalatine, otic, and maxillary ganglia are probably formed by groups of cells which have migr from that part of the neural crest which gives rise to the semilunar ganglion.

The **chromaffin organs.**—The tissue from which the sympathetic ganglia formed is at first a syncytium of cells termed sympathochromaffin cells, but two varieties of cells, small and large, are differentiated from it; the small (sympathoblasts) are transformed into the sympathetic nerve-cells, the l become chromaffin cells, and, separating from the others, accumulate to f the chromaffin organs. In the gangliated trunk of the sympathetic the chrom bodies are situated in depressions in the ganglia. In connexion with certain

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

t all, of the secondary plexuses of the sympathetic system chromaffin organs found; the largest members of this series are the *aortic bodies*, which lie along sides of the abdominal aorta between the superior mesenteric and common c arteries; to this group ong also the *carotid glomera* rotid bodies). After birth the romaffin organs degenerate and n no longer be isolated by gross section, but chromaffin tissue n be recognised with the icroscope in the sites originally cupied by them.

FIG. 147.—A transverse section through the medulla oblongata of a human embryo. × 32. (From Kollmann's Entwickelungsgeschichte.)

The **suprarenal glands.**—Each prarenal gland consists of a rtical portion derived from e cœlomic epithelium and a edullary portion originally com- sed of sympathochromaffin sue. The cortical portion is t recognisable about the be- ning of the fourth week as a es of buds from the cœlomic s at the root of the mesen- y. Later it is completely parated from the cœlomic epi- elium and forms a suprarenal lge projecting into the cœlom tween the mesonephros and the root of the mesentery. Into this cortical portion lls from the neighbouring masses of sympathochromaffin tissue migrate along the e of its central vein to form the medullary portion of the gland.

The **nose.**—The development of the nose has already been considered (pp. 78 81).

The *olfactory nerves* are developed from the cells of that part of the ectoderm hich lines the olfactory pits; these cells undergo proliferation and give rise to hat are termed the *olfactory cells* of the nose. The axons of these cells grow into e overlying olfactory bulb and form the olfactory nerves.

FIG. 148.—A transverse section through the medulla oblongata of a human embryo. (After His.)

The **eyes.**—The rudiments of the eyes appear as a pair of hollow diverticula from e lateral aspects of the fore-brain. These diverticula are visible before the osure of the anterior neuropore; after its closure they are known as the *optic sicles*. They project towards the sides of the head, and the distal part of each

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

expands to form the *optic bulb*, while the proximal part remains narrow and constitutes the *optic stalk* (figs. 149, 150). A small area of ectoderm overlying the optic bulb becomes thickened, and ultimately separated as the *lens-vesicle*, the rudiment of the crystalline lens. The outer wall of the optic bulb increases in thickness and undergoes invagination so that the bulb is converted into a cup,

FIG. 149.—A transverse section through the head of a chick, about forty-eight hours old. (From Duval's Atlas d'Embryologie.)

optic cup, consisting of two strata of cells (fig. 150). These two strata are continuous with each other at the cup-margin, which ultimately overlaps the front of the lens and reaches as far forward as the future aperture of the pupil. The invagination is not limited to the outer wall of the bulb, but involves also its postero-inferior surface and extends in the form of a groove for some distance along the optic stalk and thus, for a time, a gap or fissure, the *chorioidal fissure*, exists in the lower part of the cup (fig. 151). Through the groove and fissure the mesoderm extends into the optic stalk and cup, and in this mesoderm an artery is developed; during the seventh week the groove and fissure close, and the artery becomes the central artery of the retina. Sometimes the chorioidal fissure persists, and when this occurs the chorioid and iris in the region of the fissure remain undeveloped, giving rise to a condition known as *congenital coloboma* of the chorioid or iris.

FIG. 150.—A transverse section through the head of a chick embryo, about fifty-two hours old. (From Duval's Atlas d'Embryologie.)

The retina is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells which assume a columnar shape, acquire pigment, and form the pigmented layer of the retina, the pigment first appearing in the cells at the edge of the cup. The cells of the inner stratum proliferate and form a layer of considerable thickness from which the nervous elements and the sustentacular fibres of the retina, together with a portion of the vitreous body, are developed. In the portion of the cup which overlaps the lens the inner stratum is not differentiated into nervous elements, but persists as a layer of columnar cells which, together with the corresponding part of the pigmented layer, form the *pars ciliaris* and *iridica retinæ*.

The cells of the inner or retinal layer of the optic cup differentiate into spongioblasts and germinal cells, and the latter by their subdivisions give rise to neuroblasts.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

spongioblasts the sustentacular fibres of Müller, the outer and inner limiting membranes, and the ground-work of the molecular layers of the retina, are formed. The neuroblasts become arranged to form the ganglionic and nuclear layers. The layer

FIG. 151.—The optic cup and the chorioidal fissure of a human embryo, about four weeks old. Ventral aspect. (Kollmann.)

of rods and cones is first developed in the central part of the optic cup, and from there gradually extends towards the cup margin. All the layers of the retina are completed by the eighth month of fœtal life.

FIG. 152.—A section through the eye of a rabbit embryo, about eighteen days old. × 30. (Kölliker.)

The optic stalk is converted into the optic nerve by the obliteration of its cavity and the growth of nerve-fibres into it. Most of these fibres are centripetal, and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are the axons of the nerve-cells of the ganglionic layer of the retina, but a fe centrifugal and are derived from nerve-cells in the brain. The fibres of the nerve receive their medullary sheaths about the tenth week after birth. The chiasma is formed by the meeting and partial decussation of the fibres of the optic nerves. Behind the chiasma the fibres are continued backwards as the tracts to the thalami and mesencephalon.

The crystalline lens is developed from the lens-vesicle, which recedes the margin of the cup, and becomes separated from the overlying ectoder mesoderm. The cells forming the posterior wall of the vesicle lengthen an

Fig. 153.—A sagittal section through the eye of a human embryo, about six weeks old. (Kollmann.)

converted into the lens-fibres, which grow forward and fill the cavity of the ves (fig. 152). The cells forming the anterior wall retain their cellular character, a form the epithelium on the anterior surface of the fully developed lens. By second month the lens is invested by a vascular mesodermal capsule, the *caps vasculosa lentis*, the anterior part of which, covering the front of the lens, is nam the *pupillary membrane*; the blood-vessels supplying the posterior part of t capsule are derived from the hyaloid artery; those for the anterior part fr the anterior ciliary arteries. By the sixth month all the vessels of the capsule atrophied except the hyaloid artery, which disappears during the ninth mon of fœtal life; after birth the position of this artery is indicated by the hyal canal, which reaches from the optic disc to the posterior surface of the lens. W the loss of its blood-vessels the capsula vasculosa lentis disappears, but sometim the pupillary membrane persists at birth, giving rise to the condition term *congenital atresia of the pupil.*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The vitreous body is developed between the lens and the optic cup. The lens-diment and the optic vesicle are at first in contact with each other, but after the osure of the lens-vesicle and the formation of the optic cup the former is withdrawn om the retinal layer of the cup; the two, however, remain connected by a network delicate protoplasmic processes. This network, derived partly from the cells the lens and partly from those of the retinal layer of the cup, constitutes the rimitive vitreous body (figs. 153, 154). At first these protoplasmic processes spring om the whole of the retinal layer of the cup, but later are limited to the ciliary egion, where by a process of condensation they appear to form the zonula ciliaris. he mesoderm which enters the cup through the chorioidal fissure and around he equator of the lens becomes intimately united with this reticular tissue, and ontributes to form the vitreous body, which is therefore derived partly from the ctoderm and partly from the mesoderm.

FIG. 154.—A section through the developing eye of a trout. (Szily.)

The aqueous chamber of the eye appears as a cleft in that part of the mesoderm hich intervenes between the lens and the ectoderm. The layer of mesoderm in ront of the cleft forms the substantia propria of the cornea, that behind the cleft he stroma of the iris and the pupillary membrane. The fibres of the Ciliaris muscle re derived from the mesoderm, but those of the Sphincter and Dilatator pupillæ re of ectodermal origin, being developed from the cells of the pupillary part of the ptic cup.

The sclera and chorioid are derived from the mesoderm surrounding the optic cup.

The eyelids are formed as small cutaneous folds (fig. 152). About the middle f the third month their edges come together and unite in front of the cornea; they emain united until about the end of the sixth month.

The epithelium of the alveoli and ducts of the lacrimal gland arise as a series f tubular buds from the ectoderm of the superior conjunctival fornix; these buds re arranged in two groups, one forming the superior or orbital, and the other the nferior or palpebral, part of the gland. The lacrimal sac and nasolacrimal duct esult from a thickening of the ectoderm in the *naso-optic furrow* between the lateral asal and maxillary processes (p. 79). This thickening forms a solid cord of cells hich sinks into the mesoderm; during the third month the central cells of the ord break down, and a lumen, the naso-lacrimal duct, is established. The lacrimal ucts or canaliculi arise as buds from the upper part of the cord of cells and econdarily establish openings (puncta lacrimalia) on the margins of the lids; the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

th the result that the utricle and saccule ultimately communicate with each her by means of a Y-shaped canal. The saccule opens into the cochlear duct, rough the canalis reuniens; the semicircular ducts communicate with the utricle. The mesoderm surrounding the various parts of the epithelial labyrinth is nverted into a cartilaginous ear-capsule, and this is finally ossified to form the ny labyrinth. The portion of the psule which envelopes the semi- rcular canals chondrifies before hat which surrounds the cochlea. or a time the cartilaginous capsule incomplete, and the cochlear, estibular, and genicular ganglia are tuated in the gap between its nalicular and cochlear parts. hese ganglia are soon covered by outgrowth of cartilage and at e same time the facial nerve is idged by a growth of cartilage om the cochlear to the canalicular rts of the capsule. In the em- yonic connective tissue between e cartilaginous capsule and the thelial wall of the labyrinth the erilymphatic spaces are developed. treeter* states that the rudiment the vestibular perilymphatic pace, or *periotic cistern* as he iggests this space should be named, an be seen in an embryo of from 0 to 40 mm. in length, in the reticulum between the saccule and the fenestra estibuli. The scala tympani is next developed, and begins opposite the fenestra ochleæ; the scala vestibuli is the last to appear. The two scalæ gradually xtend along either side of the ductus cochlearis and when they reach its tip, an opening which represents the helicotrema, is developed between them. The modiolus and the osseous spiral lamina of the cochlea are not preformed in cartilage but are ossified directly from connective tissue.

FIG. 159.—The left membranous labyrinth of a human embryo, 30 mm. long. (From a model by W. His, jun.)

FIG. 160.—The tubercles from which the different parts of the auricula are developed. (His.)

2. Tubercles on mandibular arch. 3. Tubercle above groove. 3, c. Prolongation of 3 downwards. 4, 5, 6. Tubercles on hyoid arch. *o.v.* Auditory vesicle.

The auditory tube and tympanic cavity were formerly regarded as being derived from the first pharyngeal pouch, but Frazer† has recently pointed out that they are developed from a recess, the *tubotympanic recess*, between the first and third visceral arches, the floor of the recess consisting of the first and second arches and the first and second pharyngeal pouches. By the forward growth of the third arch the inner part of the recess is narrowed to form the tubal region, and the inner part of the second arch is excluded from this portion of the floor. The outer part of the recess is subsequently developed into the tympanic cavity, and the floor of this part forms the outer wall of the tympanic cavity up to about the level of the chorda ympani nerve. From this it will be seen that the outer wall of the tympanic avity has both first and second arch elements in it, the share taken by the rst arch being limited to the part in front of the handle of the malleus. The

area of the second arch includes the outer wall behind this, and turns on t back wall to take in the tympanohyal region.' During the sixth or seventh m the tympanic antrum appears as an upward and backward expansion o tympanic cavity.

The opinion generally held as to the development of the ossicles o middle ear is that the *incus* and *malleus* are derived from the dorsal e

FIG. 161.—The left auriculæ of human embryos, estimated to be thirty-fi and thirty-eight days old respectively. (After His.)

the mandibular (Meckel's) cartilage (fig. 116), the incus representing the qua bone of birds and reptiles. The *stapes* is developed from the dorsal end o cartilage of the second or hyoid arch, and first appears as a ring (annulus stap encircling a small vessel, the stapedial artery, which subsequently undergoes atro

The external acoustic meatus is developed from the first branchial or pharyngeal groove. The lower part of this groove extends inwards as a fu shaped tube (primary meatus) from which the cartilaginous portion and a s part of the roof of the osseous portion of the meatus are developed. From lower part of the funnel-shaped tube a solid epidermal plug extends downw and inwards along the floor of the tubotympanic recess; by the breaking dow the central cells of this plug the inner part of the meatus (secondary meatu produced, while the deepest cells of the e dermal plug form the epidermal stratum o tympanic membrane. The fibrous stratu the tympanic membrane is formed from mesoderm which extends between the m plate and the entoderm of the floor o tubotympanic recess.

FIG. 162.—The auricula in a more advanced stage of development than those represented in fig. 161.

The auricula or pinna is developed by gradual differentiation of six tubercles (fig. which appear around the margin of the branchial groove. Two tubercles appear the posterior edge of the mandibular a these represent the rudiments of the tragus crus helicis. Three are found on the h arch, and indicate, from below upwards, lobule, antitragus, and antihelix. One a dorsal to the first branchial groove, and g downwards behind the antitragus and antihe from it and its downward prolongation helix is developed (figs. 161, 162). S observers, however, maintain that the lowest tubercle on the hyoid arch beco the antitragus, and that the lobule is developed later as an independent forma The rudiment of the *acoustic nerve* appears about the end of the third wee the acoustic ganglion which is closely applied to the cephalic edge of auditory vesicle; the cells of this ganglion are probably derived from the ectod

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the auditory vesicle. The acoustic ganglion divides into the vestibular ganglion d the spiral ganglion of the cochlea; their nerve-cells are bipolar, each sending proximal fibre into the neural tube, and a distal fibre to the epithelial cells of e auditory vesicle.

THE DEVELOPMENT OF THE VASCULAR SYSTEM

The blood-corpuscles and the blood-vessels first make their appearance between e entoderm and the mesoderm in three regions, viz.: (*a*) on the surface of the lk-sac, (*b*) in the body-stalk, and (*c*) in the chorion.* The cells become arranged to solid strands or cords, which llectively form what His termed e *angioblast*. These strands join form a close-meshed network, e *area vasculosa*, which covers the tire yolk-sac. The peripheral ls of the strands become flat-ed and joined to each other their edges to form the endo-elium of the walls of the primi-e blood-vessels. Fluid collects thin the strands and converts em into tubes, and the more ntrally situated cells of the strands are thus pushed to the sides of the vessels d appear as masses of loosely-arranged cells projecting towards the lumen of e tube. These masses are termed *blood-islands* (figs. 163, 164); their cells are tached to form the primary blood-corpuscles (mesamœboids of Minot). The rliest blood-vessels, therefore, are formed at several separate centres; from e walls of these vessels buds grow out, become vascularised and converted into w vessels, and join with those of neighbouring areas to form a close meshwork. ang † maintains that in the ferret embryo there is evidence to show that the gins of the blood-corpuscles and the endothelium of the blood-vessels are separate and distinct—the blood-corpuscles arising from the entoderm, and the vascular endothelium from the mesoderm; the blood-corpuscles are engulfed by the endothelium of the growing vessels and in this way enter their lumina. His was of opinion that the vessels within the embryo were developed as extensions of this network, but probably they arise independently. Most observers agree that, after the aortæ have appeared, no other dependent vessels are laid down, i.e. all new vessels are derived from pre-isting ones.

FIG. 163.—A section through the vascular area to show the differentiation of the primitive vascular cells. Diagrammatic.

FIG. 164.—A section through a developing blood-vessel. Diagrammatic.

The red and the colourless corpuscles of the blood are derived from the *mesamœ-ds*. The earliest blood-corpuscles are thus all nucleated; they are also capable subdivision and of executing amœboid movements. Some mesamœboids acquire louring matter (hæmoglobin); their nuclei disintegrate and are extruded, and e non-nucleated red corpuscles or erythrocytes result. Other mesamœboids ain their nuclei; some remain in the blood as the leucocytes; others wander t into the tissues, particularly into the liver, the lymphoid tissues, and the arrow of the bones, where they form specialised collections from which the rpuscles of the blood are regenerated. From the mesamœboids five chief forms

The red lines are the dorsal aortæ continued into the umbilical arteries. The red dotted lines are the ventral aortæ, and the blue dotted lines the vitelline veins.

Minot describes stages in the develop the red blood-corpus (*a*) *the ichthyoid* blo containing granular and representing the nent blood-cells of fish the *sauroid blood-cel* rived from but small the former; they rep the permanent blood- reptiles, and their contain a dense netw chromatin which stain deeply; (*c*) the *blood-p* or early red blood-corp which are at first sp in shape; they are non- ated and found onl mammals.

The earliest stage the development of human heart and b vessels have not yet seen, but it may be sumed that they are lar to those occurrin other mammals. As al stated (p. 109), b vessels are first deve in the wall of the yolk and in the body-stalk chorion, and it is st matter of doubt wh the blood-vessels w the embryo arise as ex sions from those of yolk-sac (His), or are veloped from vascular *in situ*, and subsequ establish connexions w those of extra-embry origin.

The first rudimen the heart appears in form of a pair of tub vessels (primitive ao which are developed i a mass of cells in splanchnopleure of pericardial area (fig. These two vessels backwards, one on e side of the notochord, pass into the body- along which they carried as the umb arteries to the chorion

By the forward gr and flexure of the head the pericardial area and the anterior portions of the prim aortæ are folded under the head and come to lie on the ventral aspect of the fore-

and each vessel now consists of a ventral part, a dorsal part, united by an arch; these three parts are named respectively the ventral aorta, the dorsal aorta, and the first aortic arch. The first aortic arches pass through the mandibular arches,

FIG. 167.—A human embryo, about fourteen days old, with yolk-sac. (After His.)

and behind them five additional pairs subsequently develop, so that altogether six pairs of aortic arches are formed.

In the pericardial region the two primitive aortæ, which from the first lie close together, come into contact and the partition between them disappears, and thus a single tubular heart is formed (fig. 168); from the cephalic end of the heart the ventral aortæ arise and into its caudal end the umbilical and vitelline veins pour their contents.

FIG. 168.—The head of a chick embryo, about thirty-eight hours old. Ventral aspect. × 26. (From Duval's Atlas d'Embryologie.)

Eternod * described the circulation in a human embryo which measured 1·3 mm. in length and was devoid of mesodermal somites (fig. 166). The rudiment of the heart was situated immediately below the fore-gut and consisted of a short stem.

It gave off two vessels, the primitive aortæ, which ran backwards, one on side of the rudiment of the notochord, and then passed into the body-stalk, which they were carried to the villi of the chorion. From the chorionic vi blood was returned by a pair of umbilical veins which united in the body-st form a single vein (vena umbilicalis impar); on reaching the embryo thi

Fig. 169.—The heart of an early embryo, to illustrate its simple tubular condition. (From an Ecker-Ziegler model.)

Fig. 170.—The heart of a human embryo, about fourteen days old. (From a model by His.)

divided into two which encircled the mouth of the yolk-sac and opened into heart. At the junction of the yolk-sac and body-stalk each vein was joined transitory vitelline vein from the vascular plexus of the yolk-sac. The transi vitelline veins are replaced by the true vitelline veins which return the blood the yolk-sac, and enter the embryo through the anterior wall of the umbi orifice (figs. 167, 168). They then traverse the septum transversum, a ban mesoderm which lies between the pericardium and the yolk-sac; in this sep each vitelline vein unites with the corresponding umbilical vein to form the *com*

Fig. 171.—The heart of a human embryo, about fifteen days old. (From a reconstruction by His.)

vitello-umbilical vein which opens into the caudal end (sinus venosus) of the tub heart. The vitello-umbilical veins are soon joined by a pair of anterior cardi (primitive jugular) veins from the head, and a little later each anterior cardinal v is joined by a posterior cardinal vein from the trunk and limbs, and the short tru (duct of Cuvier) formed by the union of these two veins opens into the correspondi

llo-umbilical vein. The sinus venosus expands in a transverse direction and rporates the adjoining parts of the vitello-umbilical veins which come to form right and left horns of the sinus; into the horns of the sinus the three venous nks, viz. the vitelline vein, the umbilical vein and the duct of Cuvier, open. The r is developed in the septum transversum, and in the course of its development vitelline and umbilical veins undergo important transformations which will be plained later (p. 124).

With the atrophy of the yolk-sac the vitelline circulation diminishes and ultitely ceases, and an increasing amount of blood is carried through the umbilical eries to the villi of the chorion. Subsequently, as the non-placental chorionic li atrophy, their vessels disappear; and then the umbilical arteries convey the ole of the blood from the embryo to the placenta, whence it is returned to the bryo by the umbilical veins.

FIG. 172.—The heart of a human embryo, about thirty-five days old. Dorsal aspect. (From a model by His.)

The **further development of the heart.**—The simple tubular heart, already deibed (p. 111), elongates and bends so as to form an S-shaped loop, the anterior part nvex ventrally and to the right, and the posterior, dorsally and to the left (fig. 170). e intermediate portion arches transversely from left to right, and then turns rply forward into the anterior part of the loop. Slight constrictions make their pearance in the tube and divide it from behind forwards into five parts, viz.: the *sinus venosus*; (2) the *atrium*; (3) the *ventricle*; (4) the *bulbus cordis*, and the *truncus arteriosus* (fig. 170). The constriction between the atrium and ntricle constitutes the *atrial canal* (fig. 172), and indicates the site of the future rioventricular valves.

The sinus venosus is situated in the septum transversum behind the atrium, d opens into the latter by a median aperture. The sinus is at first placed transrsely but soon assumes an oblique position and a crescentic shape (fig. 172); right half or horn increases in size more rapidly than its left, and the sinus opens o the right portion of the atrium. The right horn of the sinus is ultimately orporated with and forms a part of the right atrium, the line of union between and the auricula being indicated in the interior of the adult atrium by a vertical st, the *crista terminalis* of His. The left horn, which ultimately receives only left duct of Cuvier, persists as the coronary sinus (fig. 172). The vitelline and bilical veins are later replaced by a single vessel, the inferior vena cava, and the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

three veins (inferior vena cava and right and left ducts of Cuvier) open in dorsal part of the atrium by a common slit-like aperture (fig. 173). The upp of this aperture represents the opening of the permanent superior vena ca

FIG. 173.—The heart of a human embryo, about thirty days old. The inter of the dorsal half. (From a model by His.)

lower that of the inferior vena cava, and the intermediate part the orifice coronary sinus. The slit-like aperture lies obliquely, and is guarded by two the *right* and *left venous valves*; above the opening these unite with each othe are continuous with a fold named the *septum spurium*; below the opening the to form a triangular thickening—the *spina vestibuli*. The right venous va retained; its cephalic portion, together with the septum spurium, forms the terminalis already mentioned. A small septum, the *sinus septum*, grows

the left venous valve disappear; the lower one-third is continued into the spina stibuli, and later fuses with the septum secundum of the atria and takes part the formation of the limbus fossæ ovalis.

The atrial canal is at first a short straight tube connecting the atrial with the ntricular portion of the heart, but its growth being relatively slow, it is gradually erlapped by the atria and ventricles so that its position on the surface of the art is indicated only by an annular constriction (fig. 174). Its lumen is reduced a transverse slit, and two thickenings, or *endocardial cushions* (fig. 173), appear, e on its dorsal, and the other on its ventral wall. These endocardial cushions oject into the atrial canal, and, meeting in the middle line, unite to form the *ptum intermedium*, which divides the canal into two channels, the future right d left atrioventricular orifices.

Fig. 175.—The heart of a human embryo, about thirty-five days old. The interior of the dorsal half. (From a model by His.)

The atrium grows rapidly, and by its lateral expansion partially encircles the lbus cordis. The latter thus comes to lie in a groove which is the first indication the ultimate division of the atrium into right and left chambers, the division ing effected by a septum, the *septum primum* (figs. 173, 175), which grows from e dorsal to the ventral wall of the cavity. For a time the atria communicate ith each other by an opening, the ostium primum of Born, in front of the free argin of the septum primum. This opening is closed by the union of the septum imum with the septum intermedium, but before this closure occurs a new opening developed in the dorsal part of the septum primum; this new opening is known the foramen ovale (ostium secundum of Born) and persists until birth. A escentic septum, the *septum secundum* (fig. 176), grows from the upper and dorsal all of the atrium immediately to the right of the septum primum and foramen vale. The horns of this crescentic septum fuse with the ventral part of the septum imum, and the intervening free part of the septum secundum overlaps the foramen vale and septum primum; the dorsal part of the latter septum acts as a flap-like lve which allows the blood to flow from the right into the left atrium, but not an opposite direction. After birth, the free edge of the septum secundum blends ith the septum primum and the foramen ovale is closed; sometimes the fusion incomplete and the upper part of the foramen remains patent.

When the heart assumes its S-shape the bulbus cordis lies in front of and ventral to the ventricle. The adjacent walls of the bulbus cordis and ventricle approximate and fuse, and the fused portion projects as a ridge, the *bulboventricular ridge*, between the bulbus cordis and the ventricle; the narrow passage which

FIG. 178.—A diagram showing the relations at an early stage between the atrioventricular opening and ventricles, the cavity of the bulbus cordis, and the bulboventricular ridge. The endocardial cushions at the distal end of the bulb are shown in a more differentiated state than they really exhibit at this stage. (J. Ernest Frazer.)

nnects these cavities is placed at the right of the atrioventricular orifice (fig. 178). he bulboventricular ridge soon disappears, and the opening from the ventricle into e bulbus cordis is widened, and lies over the right half of the atrioventricular pening (fig. 179). By the upgrowth of the ventricular septum the bulbus cordis in great measure separated from the left ventricle, but remains an integral part the right ventricle, of which it forms the infundibulum (fig. 177).

The truncus arteriosus and bulbus cordis are divided by a septum which makes s appearance in three portions. (1) Two ridge-like thickenings project into the men of the distal part of the truncus arteriosus; these increase in size and ultiately meet and fuse to form the *aortopulmonary septum* (fig. 176), which takes a

FIG. 179.—A diagram to show the intermediate stages of the aortic and pulmonary channels. (J. Ernest Frazer.)

piral course towards the proximal end of the truncus arteriosus. It divides the uncus arteriosus into the aorta and the pulmonary artery. (2) Four endocardial ushions, anterior, posterior, right and left, appear at the distal end of the bulbus ordis (fig. 178). The right and left cushions meet and fuse to form the *distal bulbar*

septum which is joined by the aortopulmonary septum. (5) Two endocardial the *right and left bulbar ridges*, develop in the bulbus cordis (fig. 179) and unite the *proximal bulbar septum* which is continuous above with the distal septum. Its lower edge fuses with the ventricular septum and brings the ventricle into communication with the pulmonary artery, and through the with the sixth pair of aortic arches; while the left ventricle is brought in tinuity with the aorta, which communicates with the remaining aortic The completed ventricular septum consists of a lower, muscular, and an membranous, part; the former is developed from the septum inferius, the from the bulbar septum.

FIG. 180.—A human embryo estimated to be twenty or twenty-one days o Right lateral aspect. (After His.)

The valves of the heart.—The atrioventricular valves are developed in relati the atrial canal. By the upward expansion of the bases of the ventricles the becomes invaginated into the ventricular cavities. The invaginated margin the rudiments of the lateral cusps of the atrioventricular valves; the med septal cusps of the valves are developed as downward prolongations of the se intermedium (fig. 181). The aortic and pulmonary semilunar valves are fo from the four endocardial cushions which appear at the distal end of the b cordis. When the aortopulmonary septum unites with the distal bulbar se the lateral endocardial cushions are each divided into two, thus giving rise thickenings—the rudiments of the semilunar valves—three at the aortic and at the pulmonary orifice.

Applied Anatomy.—In rare cases portions of the various cardiac septa may develop, or some of the endocardial cushions may fuse in an abnormal manner giving

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

various forms of congenital heart disease. Thus, the ventricular septum may fail almost irely, and a heart with but one ventricle results; more commonly the failure is only tial, leaving a patent septum ventriculorum. Various degrees of patency of the foramen

FIG. 181.—Section of a fœtal heart. (His.)

le have also been noted. Stenosis (narrowing) of the aortic and pulmonary orifices y possibly be related to defective development of the bulbus cordis; sometimes there y be only two cusps in the aortic or pulmonary valves. Complete atresia (non-perfora-n) of the pulmonary orifice is a very rare anomaly.

FIG. 182.—A scheme of the aortic arches and their transformations. (Modified from Kollmann.)

The **further development of the arteries.**—Recent observations show that none the main vessels of the adult arise as single trunks in the embryo. At the site of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

each vessel a capillary network forms, and by the enlargement of definite p this network the larger arteries and veins are developed. The branches main arteries are not always simple modifications of the vessels of the ca network, but may arise as new outgrowths from the enlarged stem.

It has been seen (p. 111) that each primitive aorta consists of a vent a dorsal part which are continuous through the first aortic arch. The dorsa at first run backwards separately on either side of the notochord, but in th week they fuse from about the level of the fourth thoracic to that of the lumbar segment to form a single trunk, the descending aorta. The first

FIG. 183.—A diagram showing the origins of the main branches of the caro arteries. (Founded on Tandler by T. H. Bryce.) (From Quain's Eleme of Anatomy, vol. i., Embryology.)

arches run through the mandibular arches, and behind them five additional pai developed within the corresponding visceral arches; so that, in all, six pairs of arches are formed (figs. 180, 182). The fifth arches are very transitory v connecting the truncus arteriosus with the dorsal ends of the sixth arches. first and second arches pass between the ventral and dorsal aortæ, while the arise at first by a common stem from the truncus arteriosus, but end separat the dorsal aortæ. As the neck elongates, the ventral aortæ are drawn out, an third and fourth arches arise directly from these vessels.

In fishes the aortic arches persist and give off branches to the gills, in whic blood is oxygenated. In mammals some of the arteries remain as perm structures, while others disappear or are obliterated (fig. 182).

The ventral aortæ.—These persist on both sides. The right ventral aorta f as far as the fourth aortic arch, the innominate artery, and beyond that arc

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

t common and external carotid arteries. The left gives rise to (*a*) the portion he aortic arch between the origins of the innominate and left common carotid ries; (*b*) the left common and external carotid arteries.

The aortic arches.—The first and second arches disappear, but the dorsal end he second gives origin to the stapedial artery (fig. 183), a vessel which atrophies nan but persists in some mammals (e.g. the rat).

The stapedial artery passes through the ring of the stapes and divides into supra-ital, infra-orbital, and mandibular branches which follow the three divisions of the eminal nerve. The infra-orbital and mandibular branches arise from a common n, the terminal part of which anastomoses with the external carotid. On the teration of the stapedial artery this anastomosis enlarges and forms the internal illary artery, and the branches of the stapedial artery are now branches of this vessel. common stem of the infra-orbital and mandibular branches passes between the two s of the auriculotemporal nerve and becomes the middle meningeal artery; the inal supra-orbital branch of the stapedial artery is represented by the orbital twigs of middle meningeal artery.

The third aortic arch constitutes the commencement of the internal carotid ry, and is therefore named the *carotid arch*. The fourth right arch forms the t subclavian as far as the origin of its internal mammary branch, while the fourth arch constitutes the arch of the aorta between the origin of the left common tid artery and the termination of the ductus arteriosus. The fifth arch dis-ears on both sides. The sixth right arch disappears; the sixth left arch gives the pulmonary arteries and forms the ductus arteriosus; this duct remains vious during fœtal life, but is obliterated a few days after birth and forms the mentum arteriosum of the adult. His showed that in the early embryo the h arch on either side gives a branch to the corresponding lung, but later both monary arteries take origin from the left arch.

The dorsal aortæ.—In front of the third aortic arches the dorsal aortæ persist form the continuations of the internal carotid arteries; these arteries pass to the in, and each divides into an anterior and a posterior branch, the former giving off ophthalmic artery and the anterior and middle cerebral arteries, while the latter ns back and joins the cerebral part of the vertebral artery. Behind the third h the right dorsal aorta disappears as far as the point where the two dorsal aortæ e to form the descending aorta. The part of the left dorsal aorta between the third fourth arches disappears, while the remainder persists to form the descending t of the arch of the aorta. A constriction, the *aortic isthmus*, is sometimes n in the aorta between the origin of the left subclavian artery and the attachment he ductus arteriosus.

Sometimes the right subclavian artery arises from the aortic arch distal to the in of the left subclavian and passes upwards and to the right behind the trachea œsophagus. This condition may be explained by the persistence of the right sal aorta and the obliteration of the fourth right arch.

In birds the fourth right arch forms the arch of the aorta; in reptiles the rth arch persists on both sides and gives rise to the double aortic arch in these mals.

The heart originally lies on the ventral aspect of the pharynx, immediately dal to the stomodæum (fig. 180); with the elongation of the neck and the develop-nt of the lungs it recedes within the thorax, and, as a consequence, the anterior tral aortæ are drawn out and the original position of the fourth and fifth arches reatly modified. Thus, on the right side the fourth arch recedes to the root of neck, while on the left side it is withdrawn within the thorax. The recurrent ves originally pass to the larynx under the sixth pair of arches, and are therefore led backwards with the descent of these structures, so that in the adult the left ve hooks round the ligamentum arteriosum; owing to the disappearance of the h and the sixth right arches the right nerve hooks round that immediately above m, i.e. the commencement of the subclavian artery.

The primitive dorsal aortæ give off ventral, dorsal, and lateral groups of mental arteries.

The *ventral* segmental arteries, the first to be developed, are originally paired sels, but, after the fusion of the dorsal aortæ, appear as unpaired trunks; they distributed to the primitive digestive tube and to the wall of the yolk-sac. ee of them persist and constitute the coeliac, superior mesenteric, and inferior

he cervical portion of the vertebral artery is developed from a longitudinal stomosis between the first seven dorsal segmental arteries. The second dorsal mental arteries run alongside the hypoglossal nerves to the brain and are named hypoglossal arteries. Each sends forwards a branch which forms the cerebral t of the vertebral artery and anastomoses with the posterior branch of the internal otid artery; the cerebral portions of the two vertebrals unite on the ventral face of the pons to form the basilar artery. The hypoglossal arteries atrophy, d then the cervical and cerebral parts of the vertebrals are connected by means the first pair of segmental arteries.

The *lateral* segmental arteries supply, on either side, the mesonephros or Wolffian ly and give branches to the testis (or ovary) and the suprarenal glands. One ticular (or ovarian) artery and three suprarenal arteries persist on either side. e inferior phrenic artery arises as a branch from the first, and the renal artery a branch from the third suprarenal artery. Additional renal arteries are frently present and may be looked on as branches of persistent lateral segmental eries.

The arteries of the limbs.—Several small arteries pass from the dorsal aorta into upper limb-bud, and form in it a free capillary anastomosis. Only one of these eries persists to form the arterial stem (subclavian artery) and the origin of this sistent vessel is transferred from the dorsal aorta to the seventh segmental ery. The subclavian artery is prolonged into the limb under the names of axillary and brachial arteries, and these together constitute the arterial stem the upper arm; the continuation of this stem in the forearm is represented by volar interosseous artery. A branch which accompanies the median nerve soon reases in size and forms the main vessel (median artery) of the forearm, while volar interosseous diminishes. Later the radial and ulnar arteries are developed as nches of the brachial part of the stem and coincidently with their enlargement median artery dwindles; occasionally it persists as a vessel of some size and ompanies the median nerve into the palm of the hand.

Senior has recently worked out the development of the arteries of the lower limb, d the following description is based on his observations.*

The primary arterial trunk (fig. 184) or 'axis' artery of the lower limb arises from e dorsal root of the umbilical artery, and courses along the dorsal surface of the igh, knee and leg; below the knee it lies between the tibia and the Popliteus uscle, and in the leg between the crural interosseous membrane and the Tibialis sterior muscle. It ends distally in a rete plantare, and gives off a perforating tery (ramus perforans tarsi) which traverses the sinus tarsi and forms a rete rsale. The femoral artery passes along the ventral surface of the thigh, and opens a new channel to the lower limb. It arises from a plexus of capillaries which is nnected proximally with the femoral branches of the external iliac artery, and stally with the ramus communicans superior of the axis artery. At the proximal rgin of the Popliteus the axis artery gives off two vessels, viz.: the posterior perficial tibial, and the posterior superficial peroneal arteries, and at the distal rgin of the same muscle it supplies a perforating branch (ramus perforans cruris) the front of the leg. A middle and an inferior communicating artery pass from the perficial peroneal to the axis artery, the former at the distal border of the Popliteus, d the latter at the distal border of the Tibialis posterior.

The femoral artery gradually increases in size, and coincidently with this increase most the whole of the axis artery, proximal to the ramus communicans superior sappears; the root of the axis artery, however, persists as the inferior glutæal tery. Two other segments of the distal part of the axis artery are maintained; e, just beyond the ramus communicans superior, which forms the proximal part the popliteal artery, the other, near the ankle, which forms a part of the peroneal tery.

The proximal portions of the posterior superficial tibial and posterior superficial roneal arteries fuse and form (*a*) the distal part of the popliteal artery, and (*b*) the st part of the posterior tibial artery, i.e. as far as the point where it gives off the roneal artery. The posterior superficial tibial artery ends in the medial plantar tery, and is largely retained to form the greater part of the posterior tibial artery. he posterior superficial peroneal artery ends in the lateral plantar artery, but e latter vessel is subsequently transferred to the posterior tibial artery. The

part of the posterior superficial peroneal artery just distal to its fusion w posterior superficial tibial forms the proximal part of the peroneal arte remainder of the latter vessel consisting of (*a*) the ramus communicans i (*b*) a short persistent part of the axis artery, and (*c*) the distal portion of the p superficial peroneal artery and its lateral calcaneal branch. The anterio artery is derived from (*a*) the ramus communicans medius, (*b*) a short sectio axis artery, (*c*) the ramus perforans cruris and its continuation to the ankle tibialis anterior pars distalis). The arteries which are distributed on the of the foot are derived from the rete dorsale, while the plantar arch and its branches originate from the rete plantare.

The **further development of the veins.**—The principal veins of the embryo divided into two groups, visceral and parietal.

Fig. 185.—The liver, and the veins in connexion therewith, of a human embry twenty-four or twenty-five days old. Ventral aspect. (After His.)

The visceral veins are the two vitelline veins bringing the blood from the yo and the two umbilical veins returning the blood from the placenta; these veins open close together into the sinus venosus.

The vitelline veins run upwards at first in front, and subsequently on side, of the digestive tube. They unite on the ventral surface of the tube beyond this are connected to one another by two anastomotic branches, one dorsal and the other on the ventral aspect of the duodenal portion of the inte which is thus encircled by two venous rings forming the figure 8 (fig. 185): the middle or dorsal anastomosis the superior mesenteric vein opens. The po of the veins above the upper ring become connected with a plexus of small cap like vessels termed *sinusoids* which form in the developing liver. The v conveying the blood to this plexus are named the *venæ advehentes*, and becom branches of the portal vein; while the vessels draining the plexus into the venosus are termed the *venæ revehentes*, and form the future hepatic veins (figs 186). After a time the left vena revehens no longer communicates directly the sinus venosus, but opens into the upper part of the right vena revehens hepatic vein). The persistent part of the upper venous ring, above the open the superior mesenteric vein, forms the trunk of the portal vein.

The two umbilical veins fuse to form a single trunk, the *vena umbilicalis* in the umbilical cord; this trunk divides within the embryo into the right an umbilical veins which pass forwards to the sinus venosus in the side walls o body. Like the vitelline veins, the direct connexion of the umbilical veins the sinus venosus becomes interrupted by the developing liver, and the whole

od from the yolk-sac and placenta passes through the substance of the liver before eaches the heart. The right umbilical and right vitelline veins shrivel and ppear; the left umbilical, on the other hand, enlarges and opens into the upper ous ring of the vitelline veins; with the atrophy of the yolk-sac the left vitelline n shrivels and disappears. Finally, a direct branch named the *ductus venosus* stablished between the upper venous ring and the right hepatic vein; the ductus osus enlarges rapidly and forms a wide channel through which most of the od, returned from the placenta, is carried direct to the heart without passing ough the liver. A small part of the blood from the placenta is, however, conveyed

FIG. 186.—A human embryo with the heart and anterior body wall removed to show the sinus venosus and its tributaries. (After His.)

m the left umbilical vein to the liver through the left vena advehens. The t umbilical vein and the ductus venosus are obliterated after birth, and form pectively the ligamentum teres and ligamentum venosum of the liver.

The parietal veins.—A pair of short transverse veins, named the *ducts of Cuvier*, en, one on either side, into the sinus venosus. Each of these ducts receives an cending and a descending vein. The ascending veins return the blood from the rieties of the trunk and from the Wolffian bodies, and are called *posterior cardinal* ins. The descending veins return the blood from the head, and are called the *terior cardinal* (primitive jugular) veins (fig. 187). The blood from the lower limbs collected by the right and left iliac and hypogastric veins, which, in the earlier ges of development, open into the corresponding right and left posterior cardinal ins; later, a transverse branch (the left common iliac vein) is developed between e lower parts of the posterior cardinal veins (fig. 189), and through this the blood carried into the right posterior cardinal vein. The portion of the left posterior rdinal vein below the left renal vein atrophies and disappears up to the point entrance of the left testicular vein; the portion above the left renal vein persists

Huntington and McClure * contend (1) that the right posterior cardinal vein takes no e in the development of the postrenal segment of the inferior vena cava, and (2) that rms only the cranial end of the azygos vein.

They state that a *supracardinal system of veins*, consisting of a bilateral and originally metrical venous channel, is developed dorsomedial to the posterior cardinal veins dorsolateral to the aorta. Frequent anastomoses occur between the posterior cardinal supracardinal veins, but only a single anastomosis, at about the level of the inter- ardinal anastomosis, is retained on each side of the body; this anastomosis permits d, collected by the supracardinal veins in the lumbar region, to reach the heart by of the prerenal division of the inferior vena cava. The formation of this anastomosis blishes the presence of a circumaortic venous ring, named the *renal collar*. The acardinal veins unite (*a*) caudally with the posterior cardinal veins at the level where

FIG. 189.—A diagram showing the development of the main cross branches between the cardinal veins.

latter receive the internal iliac and hypogastric veins, and (*b*) cranially at the level he renal collar, and thus there is established for a time a venous ring through which ureter passes.

he supracardinal veins soon separate into a cranial or azygos, and a caudal or lumbar, of veins, and the bilaterally symmetrical plan of the latter is replaced by an asymmetri- one which is initiated by a reduction, followed by a complete atrophy, of the left half he renal collar; the right half of this collar persists and elongates to form a part of postrenal segment of the inferior vena cava. The caudal half of the left supracardinal is drawn into and fuses with the vein of the right side, and from these fused veins the dal part of the postrenal segment of the inferior vena cava is formed.

The history of the development of the azygos veins in the cat shows "that they are ived chiefly from the supracardinals, and that in the adult cat only the proximal end the right azygos near the duct of Cuvier is derived from the posterior cardinal n."

In consequence of the atrophy of the Wolffian bodies the posterior cardinal veins inish in size; the anterior cardinal veins, on the other hand, become enlarged, ing to the rapid development of the head and brain. They are further augmented receiving the veins (*subclavian*) from the upper extremities, and so come to form chief veins of the ducts of Cuvier; these ducts gradually assume an almost tical position in consequence of the descent of the heart into the thorax. The ht and left ducts of Cuvier are originally of the same diameter, and are frequently med the *right and left superior venæ cavæ*. By the development of a transverse nch (the *left innominate vein*) between the two anterior cardinal veins, the blood

is carried across from the left to the right and becomes cardinal (figs. 189, 19
portion of the right anterior cardinal vein between the left innominate
azygos vein forms the upper part of the superior vena cava of the adult;
part of the latter vessel (i.e. below the entrance of the azygos vein) is form
right duct of Cuvier. Below the origin of the transverse branch the left
cardinal vein and left duct of Cuvier atrophy, the former constituting t
part of the left superior intercostal vein, while the latter is represented
ligament of the left vena cava (vestigial fold of Marshall) and the oblique
the left atrium (oblique vein of Marshall) (fig. 190). The oblique vein of
atrium passes downwards across the back of the left atrium to open into the
sinus, which, as already indicated, represents the persistent left horn of
venosus. Right and left superior venæ cavæ are present in some animals,
occasionally found in the adult human being.

FIG. 190.—A diagram showing the completion of the development of th
parietal veins.

The venous sinuses of the dura mater. The following description is based
given by Streeter.*

The primary blood-vessels of the head consist of a close-meshed capillary
which is drained by anastomosing loops into a pair of veins, named the *primo*
veins. Each primary head vein (fig. 191 *A*) begins on the diencephalon, and
along the side of the brain running medial to the semilunar ganglion and latera
auditory vesicle; on reaching the vagus nerve it turns sharply downwards and
into the duct of Cuvier. The part of the vein which is caudal to the vagus
the anterior cardinal vein, the cephalic portion of which forms the internal
vein. At a later stage the greater part of the original capillary plexus assu
form of three secondary plexuses—anterior, middle and posterior (fig. 191,
the middle and posterior plexuses each open by a single vein into the primar
vein. Some tributaries from the ventral part of the head also enter this vei
most important of these are the channels from the eye-region, and these
become the ophthalmic veins.

The development of the cranium and the brain membranes introduces
changes: the three main secondary plexuses are largely retained in associati
the dura mater, while superficial portions are split off to drain the surface of th
and deeper portions are specialized for the drainage of the brain-stem. Th

series of modifications is largely due to the increase in the size of the inte
An anastomosing channel between the middle and posterior plexuses form
dorsal aspect of the auditory vesicle, and the anterior and middle plexuses u
one another (fig. 191, *C*, *D*). A single large vein which is the commencem
transverse sinus drains the anterior and middle plexuses into the new anas
channel (fig. 191, *D*). The posterior part of the primary head vein, i.e.
connected with the internal jugular vein, disappears, but the anterior portio
region of the trigeminal nerve, is retained as the cavernous sinus, and into
ophthalmic veins open (fig. 191, *D*, *E*). The original stem of the middle
between the new anastomosing channel and the primary head vein, u
atrophy, but later is re-established as the superior petrosal sinus (fig. 191, *E*
The inferior petrosal sinus is a new formation, developed from a small plexus
the cavernous sinus and the internal jugular vein (fig. 191, *F*, *G*).

FIG. 192.—Three stages in the formation of the sagittal plexus, showing conversion into the superior sagittal sinus. Draining into it from below the channel from the chorioidal plexuses which becomes the straight si (fig. B.). A. From a human embryo 13·8 mm. long; B. From a hum embryo 20 mm. long; C. is a drawing of an injected and cleared specim 54 mm. long. (George L. Streeter.)

The transverse sinus at this stage can be recognized as a composite vessel from (1) the stem of the conjoined anterior and middle plexuses, (2) the anasto channel dorsal to the auditory vesicle, and (3) the stem of the posterior continued into the internal jugular vein; the second and third portions t form the sigmoid part of the sinus.

Between the growing cerebral hemispheres extensions of the anterior and plexuses of both sides meet and form the *sagittal plexus* (fig. 192, *A*, *B*), a of capillary veins which hangs down in the position of the future falx Along the dorsal margin of this curtain the superior sagittal sinus is evolv this sinus usually joins the right transverse sinus (fig. 192, *B*, *C*); al ventral free edge of the curtain the inferior sagittal sinus and the straig are formed, the latter passing into the left transverse sinus. When the hemispheres grow backwards they carry with them the sagittal sinus; the sinus extends backwards through a plexus in the tentorium cerebelli, transference of both sinuses is continued until they arrive at their adult with their point of junction at the confluence of the sinuses (torcular He The posterior plexus establishes a secondary connexion with the confluence sinuses, loses its connexion with the sigmoid part of the transverse sinus, retained as the occipital sinus.

The external jugular vein at first drains the region behind the ear (p auricular) and enters the anterior cardinal; a lateral tributary. A group o

m the face and lingual region converge to form a common vein, the linguofacial,* ch also terminates in the anterior cardinal vein. Later, cross communications elop between the external jugular and the linguofacial, with the result that the terior group of facial veins is transferred to the external jugular. The cephalic n is, for a time, a tributary of the external jugular vein, but is later diverted into axillary vein.

In early fœtal life the heart is placed directly under the head and is relatively large size. Later it assumes its position in the thorax, but lies at first in the idle line; towards the end of pregnancy it gradually becomes oblique in direction. atrial portion is at first larger than the ventricular part, and the two atria municate freely through the foramen ovale. In consequence of the communica-, through the ductus arteriosus, between the pulmonary artery and the aorta, contents of the right ventricle are mainly carried into the latter vessel instead

FIG. 193.—A scheme showing the relative positions of the primary lymph-sacs. (Based on the description given by Florence Sabin.)

to the lungs, and hence the wall of the right ventricle is as thick as that of the . At the end of fœtal life, however, the left ventricle is thicker than the right, difference which becomes more and more emphasised after birth.

The fœtal circulation and the changes which take place in the circulation after th are described in the section on Angiology.

The **lymphatic vessels.**—The lymphatic system begins as a series of sacs † at e points of junction of certain of the embryonic veins. These lymph-sacs are veloped by the confluence of numerous venous capillaries, which at first lose eir connexions with the venous system, but subsequently, on the formation of e sacs, regain them. The lymphatic system is therefore developmentally an shoot of the venous system, and the lining walls of its vessels are always dothelial.

In the human embryo the lymph-sacs from which the lymphatic vessels are rived are six in number; two paired, the jugular and the posterior lymph-sacs; e two unpaired, the retroperitoneal and the cisterna chyli. In lower mammals additional pair, the subclavian, is present, but in the human embryo these are erely extensions of the jugular sacs.

The position of the sacs is as follows (fig. 193): (1) the jugular, the first to appear, the junction of the subclavian vein with the anterior cardinal; (2) the posterior,

at the junction of the iliac vein with the posterior cardinal; (3) the retroper
in the root of the mesentery near the suprarenal glands; (4) the cisterna
opposite the third and fourth lumbar vertebræ. From the lymph-sacs th
phatic vessels bud out along fixed lines corresponding more or less close
the course of the embryonic blood-vessels. In the body-wall and in the
the intestine,* the deeper plexuses are the first to be developed; by co
growth of these, the vessels in the superficial layers are gradually formed
thoracic duct is probably formed from anastomosing outgrowths from the
sac and cisterna chyli. At its connexion with the cisterna chyli it is at first
but the vessels soon join.

All the lymph-sacs except the cisterna chyli are, at a later stage, divided
slender connective tissue bridges and transformed into groups of lymph-
The lower portion of the cisterna chyli is similarly converted, but its upper
remains as the adult cisterna.

THE DEVELOPMENT OF THE DIGESTIVE AND RESPIRATORY APPARATUS

The **digestive tube.**—As already indicated (p. 55), the primitive digestive
consists of two parts, viz.: (1) the *fore-gut*, within the cephalic flexure, and
to the heart; and (2) the *hind-gut*, within the caudal flexure (fig. 194). Be

FIG. 194.—The digestive tube of a human embryo 2·5 mm. long. (Peter Thompson.)

these is the wide opening of the yolk-sac, which is gradually narrowed and re
to a small foramen leading into the vitelline duct. At first the fore-gut and hi
end blindly; the anterior end of the fore-gut is closed by the buccophar
membrane; the hind-gut ends in the cloaca, which is similarly closed b
cloacal membrane.

The **mouth** is developed partly from the stomodæum, and partly from th
of the anterior portion of the fore-gut. By the growth of the head-end

The **salivary glands** arise as buds from the epithelial lining of the mou parotid appears during the fourth week in the angle between the maxillary and the mandibular arc submaxillary appears in t week, and the sublingual the ninth week, in the between the tongue and t dibular arch.

Fig. 198.—The floor of the pharynx of a human embryo, about thirty days old. (From a model by K. Peter.)

The **tongue** (figs. 196 consists of an anterior or and a posterior or pharyng During the third week appears, immediately bel ventral ends of the ha the mandibular arch, a swelling named the tu *impar*, which was descri His as forming the whole buccal part of the tongue. recent researches have that this part of the tongue is mainly, if not entirely, developed from of lateral lingual swellings which arise from the inner surface of the bular arch and meet in the middle line. The tuberculum impar is said t the central part of the tongue immediately in front of the foramen cæcu Hammar insists that it is purely a transitory structure and forms no part adult tongue. From the ventral ends of the fourth arch there arises a seco larger elevation, in the centre of which is a median groove or furrow. This ele named by His the *furcula*, is at first separated from the tuberculum impa depression, but later by a ridge, the *copula*, formed by the forward grow fusion of the ventral ends of the second and third arches. The poste pharyngeal part of the tongue is developed from the copula, which extends forwards in the form of a **V**, so as to embrace between its two limbs the buccal part of the tongue. At the apex of the **V** a pit-like invagination occurs, to form the thyreoid gland, and this depression is represented in the adult by the *foramen cæcum* of the tongue. In the adult the union of the anterior and posterior parts of the tongue is marked by the **V**-shaped *sulcus terminalis*, the apex of which is at the foramen cæcum, while the two limbs run lateralwards and forwards parallel to but a little behind the papillæ vallatæ.

Fig. 199.—A scheme showing the d ment of the branchial epithelial (Modified from Kohn.)

I. II, III, IV. Pharyngeal pouches.

The **thyreoid gland** is developed from a median diverticulum, which appears about the fourth week on the summit of the tuberculum impar, but later is found in the furrow immediately behind the tuberculum (fig. 196). It grows downwards and backwards as a tubular duct bifurcates and subsequently divides into a series of cellular cords, from wh isthmus and lateral lobes of the thyreoid gland are developed. As already (p. 78), the ultimobranchial bodies from the fifth pharyngeal pouches are em by the lateral lobes of the thyreoid gland, but they undergo atrophy and form true thyreoid tissue. The connexion of the diverticulum with the pha termed the *thyreoglossal duct*; by the second month the duct is obliterat upper end being represented by the foramen cæcum of the tongue, and its by the pyramidal lobe of the thyreoid gland.

The **palatine tonsils** are developed from the parts of the second phar

ches which lie between the tongue and the soft palate. The entoderm lining e pouches grows in the form of a number of solid buds into the surrounding oderm. These buds are excavated by the degeneration and shedding of their ral cells, and by this means the tonsillar crypts are formed. Lymphoid cells mulate around the pts, and are grouped form the lymphoid cles. The supraton- r fossa is a remnant he second pharyngeal ch.

The **thymus** appears he form of two flask- ped entodermal diver- la, which arise, one either side, from the d pharyngeal pouch 199), and extend alwards and back- ds into the surround- mesoderm in front of ventral aortæ. Here meet and are sub- ently joined by con- ive tissue, but there ever any fusion of the mus tissue proper. pharyngeal opening each diverticulum is obliterated, but the k persists for some e as a cellular cord. further proliferation the cells lining the erticulum, buds of s are formed, which ome surrounded and ated by the invading oderm. In the latter, nerous lymphoid cells e their appearance, are aggregated to n lymphoid follicles. se lymphoid cells are bably derivatives of entodermal cells ch lined the original rticula and their sub- sions. Additional portions of thymus tissue are sometimes developed from fourth branchial pouches. The thymus begins to atrophy about the age of erty.

FIG. 200.—Sagittal sections of the heads of early embryos of the rabbit. Magnified. (From Mihalkovics.)

A. From an embryo of 5 mm. long. B. From an embryo of 6 mm. long. C. Vertical section of the anterior end of the notochord and hypophysis, etc., from an embryo 16 mm. long. In A the buccopharyngeal membrane is still present. In B it is in the process of disappearing, and the stomodæum now communicates with the primitive pharynx. *am.* Amnion. *c.* Fore-brain. *ch.* Notochord. *f.* Anterior extremity of fore-gut, *i.* *h.* Heart. *if.* Infundibulum. *m.* Wall of brain cavity. *mc.* Mid-brain. *mo.* Hind-brain. *p.* Original position of hypophysial diverticulum, *py.* *ph.* Pharynx. *sp.e.* Spheno-ethmoidal, *bc.* Central, and *sp.o.* Spheno-occipital parts of basis cranii. *tha.* Thalamus.

The two pairs of **parathyreoid bodies** are developed as outgrowths from the third fourth pharyngeal pouches (fig. 199); the diverticula from the third pouches, g attached to the stalks of the thymus, are drawn to a lower level than those n the fourth pouches, and consequently the inferior pair of parathyreoids is ved from the third, and the superior pair from the fourth, pharyngeal pouches. Two diverticula arise from the fifth pharyngeal pouches and form what are ed the *ultimobranchial bodies* (fig. 199); the latter fuse with the thyreoid gland, do not form true thyreoid tissue.

The **hypophysis cerebri** consists of an anterior and a posterior lobe; the former derived from the ectoderm of the stomodæum, the latter from the floor of fore-brain. Previous to the rupture of the buccopharyngeal membrane a ch-like diverticulum of the ectodermal lining of the roof of the stomodæum

The dorsal part or greater curvature of the stomach, to which the dorsal mesogastrium is attached, grows much more rapidly than its ventral part or lesser curvature, to which the ventral mesogastrium is fixed. The dorsal mesogastrium expands rapidly, and the greater curvature is carried downwards and to the left, and the right surface of the stomach is now directed backwards, and the left surface forwards (fig. 206)—a change in position which explains why the left vagus nerve is found on the front, and the right vagus on the back of the

FIG. 205.—The trunk of a human embryo 17 mm. long. (After a reconstruction by Mall.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

stomach. The dorsal mesogastrium attached to the greater curvature follows its alterations in position, and hence it is greatly elongated and drawn to the left and ventralwards, and, as in the case of the stomach, the right surfaces of both the dorsal and ventral mesogastria are now directed backwards, and the left forwards. In this way a pouch, the *bursa omentalis*, is formed behind the stomach, and this increases in size as the digestive tube undergoes further development; the entrance to the pouch constitutes the future *epiploic foramen* (foramen of Winslow).

The duodenum is developed from that part of the tube which immediately succeeds the stomach; it undergoes little elongation, being more or less fixed in position by the liver and pancreas, which arise as diverticula from it; for a time its lumen is occluded by an epithelial plug. The duodenum is at first suspended by a mesentery, and projects forwards in the form of a loop; but the loop and its mesentery are subsequently displaced by the transverse colon, so that the right surface of the duodenal mesentery is directed backwards, and, adhering to the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

At this stage the small and large intestines are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.*

FIG. 209.—Diagrams to illustrate the development of the greater omentum and the transverse mesocolon.

The gut is now rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cæcum is placed immediately below the liver; about the sixth month the cæcum descends into the right iliac fossa, and the large intestine forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils

FIG. 210.—The tail-end of a human embryo, fifteen to eighteen days old. (From a model by Keibel.)

FIG. 211.—The cloaca of a human embryo, twenty-five to twenty-seven days old. (From a model by Keibel.)

the small intestine are disposed (fig. 207). Sometimes the downward progress of the cæcum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.†

* Sometimes this condition persists throughout life, and the duodenum lies entirely on the right side of the median plane, where it is continued into the jejunum; in such cases the arteries to the small intestine (jejunal and ileal) arise from the right instead of the left side of the superior mesenteric artery.

† See article by J. Ernest Frazer and R. H. Robbins 'On the factors concerned in causing rotation of the intestine in man,' *Journal of Anatomy and Physiology*, vol. L.

Further changes take place in the bursa omentalis and in the common mese and give rise to the peritoneal relations seen in the adult. The bursa ome which at first reaches only as far as the greater curvature of the stomach, ex downwards in front of the transverse colon and the coils of the small inte to form the greater omentum (fig. 208). Before the pleuroperitoneal op is closed, the bursa omentalis sends a diverticulum upwards on either side o œsophagus; the left diverticulum soon disappears, but the right is constrict and forms the *bursa infracardiaca* which may persist in the adult as a small sac within the thorax on the right side of the lower end of the œsophagus. The an layer of the transverse mesocolon is at first distinct from the posterior layer o greater omentum, but the two layers blend, and then the greater omentum be attached to the transverse colon (fig. 209). The mesenteries of the ascending descending parts of the colon disappear in the majority of cases, while that o small intestine assumes the oblique attachment characteristic of its adult cond

The lesser omentum is formed, as indicated above, by a thinning of the derm (*ventral mesogastrium*) which attaches the stomach and duodenum t anterior abdominal wall. By the subsequent growth of the liver this leaf of derm is divided into two parts, viz. the lesser omentum between the stomach liver, and the falciform and coronary ligaments between the liver and the abdo wall and Diaphragm (figs. 203, 208).

The **rectum and anal canal.**—The hind-gut is at first prolonged backw into the body-stalk as the tube of the allantois; but, with the growth and fle of the tail-end of the embryo, body-stalk, with its contained alla tube, is carried forwards to the ve aspect of the body, and consequ a bend is formed at the junctio the hind-gut and allantois. This dilates to form a pouch, which stitutes the *entodermal cloaca*; its dorsal part the hind-gut opens from its ventral part the alla passes into the body-stalk. later stage the Wolffian and Müll ducts open into the ventral porti the cloaca. The cloaca is, for a shut off from the exterior by *cloacal membrane* which is forme the apposition of a thick ectode and a thin entodermal layer, reaches at first as far forwards a future umbilicus. Behind the um cus, however, the mesoderm s quently extends to form the symphysis pubis and the lower part of the abdo wall. By the growth of the surrounding tissues the cloacal membrane com lie at the bottom of a depression, which is lined by ectoderm and named *ectodermal cloaca* (fig. 210)

Fig. 212.—The tail-end of a human embryo, eight and a half to nine weeks old. (From a model by Keibel.)

The entodermal cloaca is divided into a narrow dorsal and a wide ventral by means of a partition, the *urorectal septum* (fig. 211). This septum g downwards from the ridge separating the allantoic from the cloacal opening o intestine and, fusing with the cloacal membrane, divides the latter into an and a urogenital membrane. The dorsal part of the cloaca forms the rectum the anterior part the urogenital sinus and bladder. For a time a communic named the *cloacal duct* exists between the two parts of the cloaca below the uror septum; this duct occasionally persists as a passage between the rectum an bladder or urethra. By the upgrowth of the surrounding parts the anal p the cloacal membrane comes to lie at the bottom of a depression, the *proctod* or *anal pit*. On the absorption and disappearance of this membrane the re communicates with the anal canal (fig. 212). A small part of the hind-gut pr backwards beyond the anal membrane; it is named the *post-anal gut* (fig. and usually becomes obliterated and disappears.*

The **liver** arises as a diverticulum from the ventral surface of the fore-gut at e point where the latter joins the yolk-sac (fig. 213). This diverticulum is lined th entoderm, and grows upwards and forwards into the septum transversum which a mass of mesoderm between the vitelline duct and the pericardial cavity; the

FIG. 213.—The liver with the septum transversum. Human embryo. (After a model and figure by His.)

verticulum gives off two solid buds of cells which represent the right and the t lobes of the liver. The solid buds of cells grow into columns or cylinders, termed e *hepatic cylinders*, which branch and anastomose to form a close meshwork. is network invades the vitelline and umbilical veins, and breaks them up into eries of capillary-like vessels termed *sinusoids* (Minot), which ramify in the meshes the cellular network. By the continued growth and ramification of the hepatic linders the mass of the liver is gradually formed. The original diverticulum from e duodenum forms the bile-duct, and from this the cystic duct and gall-bladder

IG. 214.—The pancreas of a human embryo, five weeks old. (Kollmann.)

FIG. 215.—The pancreas of a human embryo, at the end of the sixth week. (Kollmann.)

se as a solid outgrowth which later acquires a lumen. The opening of the bile-ct is at first in the ventral wall of the duodenum; later, owing to the rotation the gut the opening is carried to the left and then dorsalwards to the position occupies in the adult.

As the liver undergoes enlargement, both it and the ventral mesoga are gradually differentiated from the septum transversum; and from the surface of the latter the liver projects downwards into the abdominal cavity the growth of the liver the ventral mesogastrium is divided into two parts, of the anterior forms the falciform and coronary ligaments and the poster lesser omentum. About the third month the liver almost fills the abd cavity, and its left lobe is nearly as large as its right. From this period the r development of the liver is less active, more especially that of the left lobe,

FIG. 216.—A schematic and enlarged transverse section through the body of human embryo, in the region of the mesogastrium. At the beginning the third month. (Modified from Toldt.)

actually undergoes some degeneration and becomes smaller than the right; b to the end of fœtal life the liver remains relatively larger than in the adult.

The **pancreas** (figs. 214, 215).—The pancreas is developed in two parts, a and a ventral. The former arises as a diverticulum from the dorsal wall duodenum a short distance above the hepatic diverticulum, and, growing up and backwards into the dorsal mesogastrium, forms the whole of the body a of the pancreas and a part of the head and uncinate process. The ventra appears in the form of a diverticulum from the primitive bile-duct at the spot the latter opens into the duodenum; from the ventral pancreas the rem of the head and uncinate process of the pancreas are developed. The duct dorsal part (accessory pancreatic duct) therefore opens directly into the duod while that of the ventral part (pancreatic duct) opens with the bile-duct.

FIG. 217.—A schematic and enlarged transverse section through the same regio as in fig. 216, at end of the third month. (Modified from Toldt.)

the sixth week the two parts of the pancreas meet and fuse, and a communic is established between their ducts. After this has occurred the terminal p the accessory duct, i.e. the part between the duodenum and the point of me of the two ducts, undergoes little or no enlargement, while the duct of the ve part increases in size and forms the main duct of the gland. The opening accessory duct into the duodenum is sometimes obliterated, and even wh remains patent it is probable that the whole of the pancreatic secretion is conv through the pancreatic duct.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

At first the pancreas is directed upwards and backwards between the two layers the dorsal mesogastrium, which give to it a complete peritoneal investment, d its surfaces look to the right and left. With the change in the position of e stomach the dorsal mesogastrium is drawn downwards and to the left, and the ht side of the pancreas is directed backwards, and the left forwards (fig. 216). e right surface becomes applied to the posterior abdominal wall, and the ritoneum which covers it undergoes absorption (fig. 217); and thus, in the adult, e gland lies behind the peritoneal cavity.

The **spleen** (fig. 204).—Although the spleen belongs to the group of ductless nds, its development may be conveniently referred to here. It appears about e fifth week as a localised thickening of the mesoderm in the dorsal mesogastrium ove the tail of the pancreas. With the change in position of the stomach the leen is carried to the left, and comes to lie behind the stomach and in contact th the left kidney. The part of the dorsal mesogastrium which intervened tween the spleen and the greater curvature of the stomach forms the gastrosplenic ament (gastrosplenic omentum).

FIG. 218.—The head and neck of a human embryo thirty-two days old. Ventral aspect. The floor of the mouth and the ventral wall of the pharynx have been removed. (His.)

The **respiratory organs.**—The rudiment of the respiratory organs appears in e fourth week as a median *laryngotracheal groove* in the ventral wall of the harynx. The groove deepens and its lips fuse to form a septum which grows om below upwards and converts the groove into a tube, the *laryngotracheal tube* g. 218), the cephalic end of which opens into the pharynx by a slit-like aperture rmed by the persistent anterior part of the groove. The tube is lined with ntoderm, and from this the epithelial lining of the respiratory tract is developed. he cephalic part of the tube forms the larynx, and its next succeeding part the rachea, while from its caudal end two lateral outgrowths, the right and left *lung-ds*, arise, and from the mesoderm surrounding them the connective tissue of the ronchi and lungs are developed.

The first rudiment of the larynx consists of two *arytænoid swellings*, which ppear, one on either side of the cephalic end of the laryngotracheal groove, nd are continuous in front of the groove with a transverse ridge (*furcula* His) which lies between the ventral ends of the fourth branchial arches nd from which the epiglottis is subsequently developed (figs. 197, 198). After e separation of the trachea from the œsophagus, the arytænoid swellings me into contact with one another and with the back of the epiglottis, and the trance to the larynx assumes the form of a T-shaped cleft, the margins of the cleft here to one another and the laryngeal centre Kangri Collection, Haridwar occluded. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

arytænoid swellings are differentiated into the arytænoid and corniculate car and the folds joining them to the epiglottis form the aryepiglottic folds in the cuneiform cartilages are developed as derivatives of the epiglottis. The th cartilage is developed from the ventral ends of the cartilages of the four fifth branchial arches; it appears as two lateral plates, each chondrified fro centres and united in the midventral line by membrane in which an add centre of chondrification develops. The cricoid cartilage arises from two c ginous centres, which soon unite ventrally and gradually extend and ulti fuse on the dorsal aspect of the tube.*

According to Frazer,† who has made an important investigation on the de ment of the larynx, the glottis or space between the vocal folds is the pr opening of the larynx. During the second and third months a lateral mass (a noid swelling), derived from the fourth and fifth arches, grows forward on eith

Fig. 219.—The lung-buds from a human embryo, about four weeks old, showing commencing lobulation. (His.)

Fig 220.—The lungs of a human emb more advanced in development. (His.

of the primary opening, and from these masses the lateral walls of the ves of the larynx are developed. A third elevation or 'central mass' is formed b the second and third arches. These three masses bound the secondary op of the larynx. In the lateral masses the arytænoid cartilages and aryepiglottic are developed; from the central mass the epiglottis is formed.

The right and left lung-buds grow out posterior to the ducts of Cuvier, and into lobules, three appearing on the right, and two on the left, lung-bud; subdivisions are the early indications of the corresponding lobes of the lungs (figs 220). The buds undergo further subdivision and ramification, and ultimatel in minute expanded extremities—the infundibula of the lung. After the month the air-sacs begin to make their appearance on the infundibula in the of minute pouches. The pulmonary arteries are derived from the sixth a arches. During the course of their development the lungs migrate in a c direction, so that by the time of birth the bifurcation of the trachea is opp the fourth thoracic vertebra. As the lungs grow they project into the pl passages or parts of the cœlom which will ultimately form the pleural sacs, an splanchnic mesoderm enveloping the lung rudiment expands on the growing and is converted into the pulmonary pleura.

THE DEVELOPMENT OF THE BODY-CAVITIES

In the human embryo described by Peters the mesoderm outside the embr disc is split into two layers enclosing the extra-embryonic part of the cœlom. appear in the embryonic part of the mesoderm, and fuse to form the intra-embr part of the cœlom. At first the two parts of the cœlom are separated from another, but later they become continuous around the orifice of the future umbi on the closure of which the continuity is again lost. The intra-embryonic p the cœlom forms the pericardial, pleural and peritoneal cavities; the e

ve the septum, and thus pleural and peritoneal portions of the cœlom (still, rever, in communication with one another) may be recognised.

The ultimate separation of the pericardial, pleural, and peritoneal cavities from another is effected by the growth of a ridge of tissue (*pulmonary ridge* of Mall) either side from the mesoderm surrounding the duct of Cuvier (figs. 221, 222). front or cephalic part of this ridge (pleuropericardial membrane) grows across obliterates the pleuropericardial opening; the hinder or caudal part (pleuro-itoneal membrane) grows across the pleuroperitoneal opening. The pleuro-itoneal openings may remain patent; fig. 224 represents a persistent left opening, ough which the spleen and left suprarenal body projected into the left pleural ity.

With the continued growth of the lungs the pleural cavities are pushed forwards he body-wall towards the ventral median line, thus separating the pericardium n the lateral thoracic walls (fig. 223). The further development of the peritoneal ity has been described with the development of the digestive tube (p. 137 eq.).

THE DEVELOPMENT OF THE UROGENITAL ORGANS

The urinary and generative organs are developed from the intermediate cell-mass h is situated between the primitive segments and the lateral plates of mesoderm. permanent organs of the adult are preceded by a set of embryonic structures

FIG. 225.—A transverse section through a ferret embryo. (A. Robinson.)

ither side; these consist of the pronephros, the mesonephros, the metanephros, the Wolffian and Müllerian ducts. The pronephros disappears very early; structural elements of the mesonephros mostly degenerate, but in their place eveloped the genital gland, in association with which the Wolffian duct remains he duct of the male genital gland, the Müllerian as that of the female; some he tubules of the metanephros form part of the permanent kidney.

The **pronephros and the Wolffian duct.**—In the intermediate cell-mass of lower thoracic and upper cervical segments short evaginations from the om grow dorsalwards into each segment. The evaginations form a series of nsverse tubules each of which communicates by means of a funnel-shaped ated opening with the cœlomic cavity, and in the course of each duct a glomerulus is developed. Secondary glomeruli are formed, and the complete group con-utes the *pronephros*. The tubules of the pronephros undergo rapid atrophy disappear. A solid rod of cells forms in the mesoderm of the lateral cell-mass, under the ectoderm and overlying the pronephros. This rod grows caudal-rds to reach the ventral part of the cloaca, and becoming canalised, forms the *lffian duct* (fig. 225). In lower vertebrates its head-end acts as a duct for the nephros and is termed the *pronephric duct*, but in man this function is in abeyance he pronephros is a rudimentary and very transitory structure, the proximal part undergoing atrophy while the distal part is still in process of formation.

The **mesonephros, Müllerian duct, and genital gland.**—On the medial side of Wolffian duct, and extending from the sixth cervical to the third lumbar

segment, the *Wolffian tubules* (fig. 226) are developed. Each tubule first ap a solid mass of cells, which later becomes hollowed in the centre; one en towards and finally opens into the Wolffian duct, the other dilates and is inva by a tuft of capillary blood-vessels to form a glomerulus. The tubules coll constitute the *mesonephros or Wolffian body* (figs. 201, 205, 227). By the

FIG. 226.—A section through the urogenital fold of a chick embryo, four days old. (Waldeyer.)

sixth week this body forms an elongated spindle-shaped structure, term *urogenital fold* (fig. 226), which projects into the cœlomic cavity on either side dorsal mesentery, from the septum transversum in front to the fifth lumbar s behind; in the medial parts of these folds the genital glands are developed Wolffian bodies persist and form the permanent kidneys in fishes and ampl but in reptiles, birds, and mammals they atrophy and for the most part dis coincidently with the development of the permanent kidneys. The atrophy during the sixth or seventh week of fœtal life and proceeds rapidly, so that beginning of the fifth month only the ducts and a few of the tubules remain.

FIG. 227.—The left Wolffian body before any distinction of sex has appeared. Anterior aspect. Enlarged. (From Farre, after Kobelt.)

In the female the Wolffian bodies and ducts atrophy. The remains of the lffian tubules are represented by the epoöphoron or organ of Rosenmüller, and paroöphoron, two small collections of rudimentary, blind tubules which are ated in the mesosalpinx (fig. 228).

e lower part of the Wolffian duct ppears, while the upper part persists he longitudinal duct of the epoöphoron uct of Gärtner * (fig. 230, B).

The **Müllerian ducts.**—Shortly after formation of the Wolffian ducts a ond pair of ducts is developed; these named the *Müllerian ducts*. Each es on the lateral aspect of the corre-nding Wolffian duct as a tubular gination of the cells lining the cœlom 226). The orifice of the invagination ains patent, and undergoes enlarge-nt and modification to form the ominal ostium of the uterine tube. e ducts pass backwards, and run at t lateral to the Wolffian ducts; to-rds the posterior end of the embryo y cross to the medial side of the lffian ducts, and run side by side ween and dorsal to them—the four ducts forming the *genital cord* (fig. 229). e Müllerian ducts end on the *Müllerian eminence*, an epithelial elevation in the tral part of the cloaca between the orifices of the Wolffian ducts; at a later e they open into the cloaca in this situation.

FIG. 229.—The urogenital sinus of a female human embryo, eight and a half to nine weeks old. (From a model by Keibel.)

* Berry Hart (*op. cit.*) has described the Wolffian ducts as ending at the site of the future en in bulbous enlargements, which he has named the *Wolffian bulbs*; and states that the en is formed by these bulbs, 'aided by a special involution from below of the cells lining urogenital sinus.' He further believes that 'the lower third of the vagina is due to the escence of the upper portion of the urogenital sinus and the lower ends of the Wolffian s,' and that 'the epithelial lining of the vagina is derived from the Wolffian bulbs.' He regards the colliculus seminalis of the male urethra as being formed from the lower part he Wolffian ducts.

In the male the Müllerian ducts atrophy, but traces of their anterior ends are resented by the appendices of the testes (hydatids of Morgagni), while their minal fused portions form the utricle which opens into the floor of the prostatic tion of the urethra (fig. 230, C).

In the female the Müllerian ducts persist and undergo further development. e portions of the ducts which lie in the genital cord fuse to form the uterus: e parts which are proximal to this cord remain separate, and each forms the responding uterine tube—the abdominal ostium of which is developed from the terior extremity of the original tubular invagination from the cœlom (fig. 230, B). e fusion of the distal parts of the Müllerian ducts begins in the third month, d the septum formed by their fused medial walls disappears from behind forwards, d thus the cavity of the uterus is produced. In some animals, and occasionally he human subject, the septum persists, giving rise to a bicornuate uterus. About fifth month an annular constriction marks the position of the neck of the uterus, d after the sixth month the lls of the uterus begin to thicken. e vagina is formed from two d extensions from the ends of Müllerian ducts; these grow first as solid cords which push r way towards the urogenital um. The ends fuse with one ther, and by the breaking wn of the central cells the cavity the vagina results, and this ity opens on the exterior through e urogenital septum; a portion the septum remains to form the men.

FIG. 231.—A transverse section through a human embryo, eight and a half to nine weeks old. (From a model by Keibel.)

The **genital glands**.—The first pearance of the genital gland is entially the same in the two kes, and consists of a thickening the epithelial layer which lines e cœlomic cavity on the medial e of the urogenital fold (fig. 226). e thick plate of epithelium *nital epithelium*) extends deeply, d, pushing the mesoderm before forms a distinct projection, med the *genital ridge* (fig. 226). From the latter the testis in the male and the ry in the female are developed. At first the mesonephros and genital ridge suspended by a common mesentery, but as the embryo grows the genital ridge gradually pinched off from the mesonephros, with which it is at first continuous, ough it still remains connected to the remnant of this body by a fold of itoneum, the *mesorchium* (*or mesovarium*) (fig. 231). The distinction of sex in e genital ridge is perceptible about the seventh week.

In a 10 mm. embryo the genital gland reaches from about the sixth to the elfth thoracic segment. It subsequently extends as far as the second sacral gment, but simultaneously with this caudal extension the cranial three-fourths the gland undergo degeneration.

The **ovary**, formed from the genital ridge, is at first a group of cells derived m the genital epithelium; later the group is differentiated into a central mass d a layer of surface epithelium (fig. 232). Between the cells of the surface ithelium a number of larger cells, the *primitive ova*, are found, and these are rried into the subjacent stroma by bud-like ingrowths (*genital cords*) of the surface ithelium (fig. 233). The surface epithelium ultimately forms the permanent thelial covering of this organ; it loses its connexion with the central mass of lls, and a tunica albuginea develops between them. The ova are chiefly derived m the cells of the central mass; these cells are separated from one another by irregularly arranged growth of connective tissue; each ovum assumes a covering connective tissue (follicle) cells, and in this way the rudiments of the ovarian licles are formed (fig. 233).

It was formerly supposed that the primitive germ-cells were derived fro cœlomic epithelium covering the genital ridge, but it has been shown that, in the vertebrates at least, they are probably formed during the later stages of cell-cle They can be distinguished from the somatic cells by the large size of their bodi nuclei, and by their cytoplasm which is only faintly granular and has no affini ordinary stains, but assumes a brownish colour when treated by osmic acid. primitive germ-cells migrate first into the root of the mesentery and from there in cœlomic epithelium covering the genital ridge. A considerable number apparently reach their proper destination, since 'vagrant germ-cells are found in all sorts of but more particularly on the mesentery.'* Some of these may possibly find the into the germinal ridge; some probably undergo atrophy, while others may persi become the seat of dermoid tumours.

The **testis** is developed in much the same way as the ovary. Like the ov its earliest stages it consists of a central mass of epithelial cells covered by a

FIG. 232.—A longitudinal section of the ovary of a cat embryo, 9·4 cm. long. Sche (After Coert, from Hertwig's Handbuch der Entwickelungslehre.)

epithelium. In the central mass a series of epithelial cords (testis-cords) a (fig. 234); simultaneously the peripheral part of the central mass is converted a tunica albuginea which intervenes between the testis-cords and the su epithelium and excludes the latter from any part in the formation of the tiss the testis. The thin inner ends of the testis-cords converge towards the f hilum and there unite in a network which ultimately becomes the rete testis. the outer parts of the testis-cords the seminiferous tubules are developed. between them connective tissue septa extend. The tubules of the rete testis be connected with outgrowths from the Wolffian body, which, as already mentio form the efferent ducts of the testis.

The descent of the testes.—The testes at an early period of fœtal life, are pl in the posterior part of the abdominal cavity, and each is attached to the m nephros by a peritoneal fold, named the *mesorchium*. From the front of mesonephros a fold of peritoneum, termed the *inguinal fold*, grows forwards to and fuse with a peritoneal fold, named the *inguinal crest*, which grows backw

* Beard, *Journal of Anatomy and Physiology*, vol. xxxviii.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

in the anterolateral abdominal wall. The testis thus acquires an indirect nexion with the anterior abdominal wall; and at the same time a portion of peritoneal cavity lateral to these fused folds is marked off as the future saccus

FIG. 233.—A section through the ovary of a new-born child. (Waldeyer.)

ginalis. In the inguinal crest a peculiar structure, the *gubernaculum testis*, akes its appearance. This is at first a slender band, extending from that part the skin which afterwards forms the scrotum, through the inguinal canal to the dy and epididymis of the testis. As development advances, the peritoneum closing the gubernaculum forms two folds, one above the testis and the other low it. The one above the stis is the *plica vascularis*, and ntains ultimately the testicular ssels. The one below, the *plica bernatrix*, contains the lower part the gubernaculum and ends at e abdominal inguinal ring in a e of peritoneum, the *saccus inalis*, which protrudes down inguinal canal. By the fifth nth the upper part of the guber- culum has disappeared, while e lower part has become a thick rd, and consists of a central re of unstriped muscle-fibres, d outside this of a firm layer striped elements, connected with e abdominal wall; as the scrotum velops, the main portion of the wer end of the gubernaculum is rried, with the skin to which it attached, to the bottom of this uch. The saccus vaginalis projects self downwards into the inguinal el, and emerges at the subcu- eous inguinal ring, pushing before a part of the Obliquus internus and the aponeurosis of the Obliquus externus, ich form respectively the Cremaster muscle and the intercrural fascia. It forms gradually elongating pouch, which eventually reaches the bottom of the scrotum, d behind this pouch the gubernaculum lies. The testis, being attached by the

FIG. 234.—A section through a genital cord of the testis of a human embryo 3·5 cm. long. (Felix and Bühler.)

Digitized by Arya Samaj Foundation Chennai and eGangotri

gubernaculum to the bottom of the scrotum, passes first into the inguin and eventually into the scrotum, invaginating the saccus vaginalis from It seems certain also that the gubernacular cord becomes shortened as devel proceeds, and this assists in causing the testis to reach the bottom of the s By the end of the eighth month the testis has reached the scrotum, and th part of the saccus vaginalis is converted into a narrow canal which is obl a short time after birth, and this o tion extends gradually downwa within a short distance of the The lower part of the saccus va is thus entirely cut off from the peritoneal cavity and constitut parietal portion of the *tunica vag*

FIG. 235.—The tail-end of a human embryo, twenty-five to twenty-nine days old. (From a model by Keibel.)

Descent of the ovaries.—In the there is also a gubernaculum, effects a considerable change position of the ovary, though extensive as that of the testis gubernaculum in the female contact with the fundus of the and contracts adhesions to this The part of the gubernaculum be the ovary and the uterus becomes t ment of the ovary, the part betwe uterus and the labium majus the round ligament of the uterus; a pouch o toneum analogous to the saccus vaginalis in the male accompanies it alo inguinal canal; it is called the *canal of Nuck.*

Applied Anatomy.—Sometimes the testes are retained within the abdomen or i canal, constituting what is known as cryptorchismus. In the female, in rare ca gubernaculum fails to contract adhesions to the uterus, and then the ovary d through the inguinal canal into the labium majus, and its position resembles tha testis.

The **metanephros and the permanent kidney.**—The rudiments of the perm kidneys make their appearance about the end of the first or the beginning second month. Each kidney has a twofold origin, part arising from the metanephros, and part as a diverticulum from the hind-end of the Wolffian duct close to where the latter opens into the cloaca (figs. 235, 236). The metanephros arises in the intermediate cell-mass, caudal to the mesonephros which it resembles in structure. The diverticulum from the Wolffian duct grows dorsalwards and cranialwards along the posterior abdominal wall, where its blind extremity expands and subsequently divides into several buds, which form the rudiments of the pelvis and calyces of the kidney; the collecting tubules are developed by continued growth and subdivision of the buds. The proximal portion o diverticulum becomes the ureter. The secretory tubules are developed fro metanephros, which is moulded over the growing end of the diverticulum the Wolffian duct. The tubules of the metanephros, unlike those of the prone and mesonephros, do not open into the Wolffian duct. One end of each t expands to form a glomerulus, while the remainder rapidly elongates to form convoluted tubule, the loop of Henle, and the junctional tubule; the last and establishes communication with one of the collecting tubules which are d from the ultimate ramifications of the diverticulum from the Wolffian duct.

FIG. 236.—The tail-end of a hum embryo, thirty-two to thirty-th days old. (From a model Keibel.)

oderm around the tubules is condensed to form the connective tissue of the ey. The ureters open at first into the hind-end of the Wolffian ducts; but r the sixth week they open independently into the part of the cloaca which nately becomes the bladder.

237, 238).

he secretory tubules of the ey are arranged into pyramidal ses or lobules, the bases of ch are at the surface of the ey, while their apices constitute renal papillæ. The lobulated dition of the kidneys exists for e time after birth and traces of ay be found in the adult. The eys of the ox and many other nals remain lobulated throughout

Fig. 237.—The tail-end of a human embryo, eight and a half to nine weeks old. (From a model by Keibel.)

he **urinary bladder** is formed ly from the entodermal cloaca partly from the ends of the fian ducts. After the separation rectum from the dorsal part e cloaca (p. 142), the ventral of the latter becomes subdivided three portions: (1) a dorsal *co-urethral portion*, continuous the allantois—into this portion the Wolffian ducts open; (2) an intermediate row channel, the *pelvic portion*; and (3) a ventral broad *phallic portion*, closed rnally by the urogenital membrane (fig. 238). The second and third parts ther constitute the *urogenital sinus*. The vesico-urethral portion incorporates hind-ends of the Wolffian ducts and the associated ends of the renal diverticula, these give rise to the trigone of the bladder and part of the prostatic urethra. remainder of the vesico-urethral portion forms the body of the bladder and part he prostatic urethra; its apex is prolonged to the umbilicus as a narrow canal, ch later is obliterated and becomes the medial umbilical ligament (urachus).

Fig. 238.—The primitive kidney and the bladder, from a reconstruction. (After Schreiner.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

he **prostate** originally consists of two separate portions, each of which arises series of buds from the epithelial lining of the urogenital sinus and vesico-hral part of the cloaca, between the third and fourth months. These buds

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

become tubular, and form the glandular substance of the two lobes which ul meet and fuse behind the urethra and also extend on to its ventral aspe isthmus or middle lobe is formed as an extension of the lateral lobes betw common ejaculatory ducts and the bladder. In the female the urethral which open into the para-urethral ducts (Skene's ducts) are believed to homologues of the prostatic glands.

FIG. 239.—Stages in the development of the external sexual organs in the m and female. (From the Ecker-Ziegler models.)

The *bulbo-urethral glands of Cowper* in the male, and *greater vestibular of Bartholin* in the female, also arise as diverticula from the epithelial lining urogenital sinus.

The **external organs of generation** (fig. 239).—As already stated (p. 14 cloacal membrane, composed of ectoderm and entoderm, originally reache the umbilicus to the tail. The mesoderm extends to the midventral line fo distance behind the umbilicus, and forms the lower part of the abdominal it ends below in a prominent swelling, the *cloacal tubercle*. Behind this t the urogenital part of the cloacal membrane separates the ingrowing sh mesoderm.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The first rudiment of the penis (or clitoris) is a structure termed the *phallus*; it is ved from the phallic portion of the cloaca which has extended on to the end and s of the under surface of the cloacal tubercle. The terminal part of the phallus, esenting the future glans penis, becomes solid; the remainder, which is hollow, is erted into a longitudinal groove by the absorption of the urogenital membrane. *In the female* a deep groove forms around the phallus and separates it from the of the cloacal tubercle, which is now termed the *genital tubercle*. The sides of genital tubercle grow backwards as the *genital swellings*, which ultimately form labia majora; the tubercle itself becomes the mons pubis. The labia minora e by the continued growth of the lips of the groove on the under surface of phallus; the remainder of the phallus forms the clitoris.

In the male the early stages are similar, but the pelvic portion of the cloaca ergoes much greater development, pushing before it the phallic portion. The ital swellings extend round between the pelvic portion and the anus, and form rotal area; during the changes associated with the descent of the testes this is drawn out to form the scrotal sacs. The penis is developed from the phallus. n the female, the urogenital membrane undergoes absorption, forming a channel the under surface of the phallus; this channel extends only as far forwards he corona glandis.

The corpora cavernosa of the penis (or clitoris) and of the urethra arise from esodermal tissue in the phallus; they are at first dense structures, but later ar spaces appear in them, and they gradually become cavernous.

The *prepuce* is formed by the growth of a solid plate of ectoderm into the erficial part of the phallus; on coronal section this plate presents the shape of orseshoe. By the breaking down of its more centrally situated cells the plate plit into two lamellæ, and a cutaneous fold, the prepuce, is liberated which ns a hood over the glans. 'Adherent prepuce is not an adhesion really, but ndered central desquamation' (Berry Hart, *op. cit.*).

The **urethra.**—As described above, in both sexes the phallic portion of the aca extends on to the under surface of the cloacal tubercle as far forwards as apex. At the apex the walls of the phallic portion come together and fuse, the en is obliterated, and a solid plate, the *urethral plate*, is formed. The remainder the phallic portion is for a time tubular, and then, by the absorption of the genital membrane, it establishes a communication with the exterior; this opening he *primitive urogenital ostium*, and extends forwards to the corona glandis.

In the female this condition is largely retained; the portion of the groove on clitoris broadens out while the body of the latter enlarges, and thus the adult thral opening is situated behind the base of the clitoris.

In the male, by the greater growth of the pelvic portion of the cloaca a longer thra is formed, and the primitive ostium is carried forwards with the phallus, it still ends at the corona glandis. Later the groove closes from behind forwards. nwhile the urethral plate of the glans breaks down centrally to form a median ve continuous with the primitive ostium. This groove also closes from behind wards, so that the external urethral opening is shifted forwards to the end of glans penis.

HE FORM OF THE EMBRYO AT DIFFERENT STAGES OF ITS GROWTH.

During the first week the ovum is in the uterine tube. Having been fertilised in the per part of the tube, it passes slowly along the tube—undergoing segmentation meanwhile nd ultimately reaches the uterus. Peters * described a specimen, the age of which he koned as from three to four days, but which was probably about fourteen days.† It s embedded in the decidua on the posterior wall of the uterus and enveloped by a decidua sularis, the central part of which, however, consisted merely of a layer of fibrin. The m was in the form of a sac, the outer wall of which consisted of a layer of trophoblast; de this was a thin layer of mesoderm composed of round, oval, and spindle-shaped s. Numerous villous processes—some consisting of trophoblast only, others possessing re of mesoderm—projected from the surface of the ovum into the surrounding decidua. de this sac the rudiment of the embryo was found in the form of a patch of ectoderm, ered by a small but completely closed amnion. It possessed a minute archenteron

* Hubert Peters, *Die Einbettung des menschlichen Eies*, 1899.

† Bryce and Teacher (*Early Development and Imbedding of the Human Ovum*, 1908) describe ovum, the age of which they estimate at 13 to 14 days; they are of opinion that the age of ers' ovum has been greatly understated, and should be reckoned as from 13½ to 14½ days.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and was surrounded by mesoderm, which was connected by a band to the lining the trophoblast (fig. 94).

By the third week the cephalic and caudal folds of the embryo are evident; groove is partly closed, and six or seven pairs of primitive segments are present

FIG. 240.—A human embryo, 2·6 mm. long. (His.)

In the fourth week the embryo is about 2·5 mm. long, and thirty pairs of segments are differentiated. The brain-vesicles and the rudiment of the auditor are visible (figs. 240, 241).

In the fifth week the embryo is markedly curved on itself; the stomodœum branchial grooves are developed; the lens-rudiment is separated from the ecto forms a closed vesicle; the rudiments of the limb-buds and of the Wolffian b visible. The crown-rump length of the embryo—i.e. the length from the verte head to the lowest part of the breech—is about 5 mm.

FIG. 241.—A human embryo, 4·2 mm. long. (His.)

By the sixth week the third and fourth branchial arches have receded from the and form the floor of the sinus cervicalis which is covered in front by the hyoid arch medial and lateral nasal processes are separated by the olfactory pits; the globular pr are approaching one another; the maxillary processes are growing forward to fuse w lateral nasal and globular processes. The three segments of each limb-bud can be reco —the development of the fore-limb being always in advance of that of the hind Towards the end of this month the rudiments of the fingers and toes are evident, a crown-rump length is about 11 mm.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In the seventh and eighth weeks the flexure of the head is gradually reduced and the k is somewhat lengthened. The upper lip is completed and the nostrils are directed wards; the palate is not completely developed. The eyelids are present in the shape olds above and below the eye, and the different parts of the auricula are distinguishable. the end of the eighth week the crown-rump length of the fœtus is about 25 mm.

FIG. 242.—A human embryo, about 10 mm. long. (His.)

In the third month the head is extended and the neck is lengthened. The eyelids meet d fuse, remaining closed until the end of the sixth month. The limbs are well developed d nails appear on the digits. The external generative organs are so far differentiated t it is possible to distinguish the sex. By the end of this month the crown-rump length the fœtus is about 10 cm.

In the fourth month the loop of gut which projected into the umbilical cord is withdrawn thin the fœtus. The hairs begin to make their appearance. By the end of the fourth nth the crown-rump length of the fœtus is about 14 cm., and the total length—i.e. luding the legs—about 22 cm.

FIG. 243.—A human embryo, about 11 mm. long. (His.)

During the fifth month the first movements of the fœtus are usually observed. The uption of hair on the head commences, and the vernix caseosa begins to be deposited. the end of this month the total length of the fœtus is nearly 30 cm.

In the sixth month the body is covered by fine hairs (*lanugo*) and the deposit of vernix eosa is considerable. The papillæ of the skin are developed and the free borders of the ils project from the corium of the dermis. From vertex to heels, the total length of the tus at the end of this month is about 33 cm. The weight is about 1 kilogram.

In the seventh month the pupillary membrane atrophies and the eyelids are open. e testis descends with the vaginal sac of the peritoneum. From vertex to heels the total gth at the end of the seventh month is about 40 cm. The weight is about 1·5 kilograms.

OSTEOLOGY

HE general framework of the body is built up mainly of a series of bones, supplemented in certain regions by pieces of cartilage; this bony and ilaginous framework constitutes the *skeleton*.

In comparative anatomy the term skeleton has a wider application, since ome of the lower animals hard, protecting and supporting structures are 'oped in association with the integumentary system. In such animals keleton consists of an internal or deep skeleton, the *endoskeleton*, and an rnal or superficial, the *exoskeleton*. In the human subject the oxeskeleton ery rudimentary, its only important representatives being the nails and enamel of the teeth, and therefore, in human anatomy, the term skeleton is fined to the endoskeleton; this is divisible into an *axial* part, which includes bones of the head and trunk, and an *appendicular* part, which comprises se of the extremities or limbs. The minute structure and the physical perties of bone are described on pages 17 to 25.

In the skeleton of the adult there are 206 bones, grouped as follows:

Axial Skeleton	Vertebral column	26	
	Skull	22	
	Hyoid bone	1	
	Ribs and sternum	25	
		—	74
Appendicular Skeleton	Upper extremities	64	
	Lower extremities	62	
		—	126
	Auditory ossicles		6
	Total		206

Bones are divisible into four classes: *long*, *short*, *flat*, and *irregular*.

The **long bones** are found in the limbs, where they form levers; each sists of a body or shaft and two ends. The *body* or *shaft* is tubular, h a central cavity termed the *medullary cavity*; the wall consists of dense, npact substance of considerable thickness in the middle part of the body the bone, but becoming thinner towards the ends; projecting into the dullary cavity is some spongy substance, scanty in the middle of the body the bone, but plentiful towards the ends. The *ends* are usually expanded, purposes of articulation and muscular attachment; they consist of spongy stance covered by thin compact bone, and are usually developed from or more secondary or *epiphysial* centres of ossification. The medullary rity and the spaces in the spongy substance are filled with marrow (*medulla ium*).

The **short bones**.—Where a part of the skeleton is intended for strength d compactness combined with limited movement, it is constructed of a mber of short bones, as in the *carpus* and *tarsus*. These bones consist of spongy stance surrounded by a thin crust of compact bone.

The **flat bones**.—Where the principal requirement of the skeleton is to tect delicate structures or provide broad surfaces for muscular attachment, bones are expanded into plates, as in the skull and the scapulæ, and are nposed of two thin layers of compact bone separated by a variable quantity

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of spongy substance. In the cranial bones, the layers of compact b familiarly known as the *tables* of the skull; the outer table is thick and the inner thin, dense, and brittle. The intervening spongy substance the *diploë*, and this, in certain regions of the skull, undergoes absorpti spaces filled with air (*air-sinuses*) are left between the two tables of the

The **irregular bones**, from their peculiar form, cannot be groupe the preceding heads. They consist of spongy substance enclosed w thin layer of compact bone.

Surface of bones.—On the surfaces of the bones there are eminen depressions, either articular or non-articular. Examples of *articular em* are the heads of the humerus and femur; and of *articular depressions* the cavity of the scapula, and the acetabulum of the hip-bone. *Non-a eminences* are designated according to their form. Thus, a broad, uneven elevation is called a *tuberosity*, *trochanter*, *protuberance*, or *proc* small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a a narrow, rough elevation of some length, a *ridge*, *crest*, or *line*. *Non-a depressions* are also of variable form, and are described as *fossæ*, *pits*, *depr grooves*, *furrows*, *fissures*, *notches*, &c.

THE VERTEBRAL COLUMN (COLUMNA VERTEBRALIS)

The **vertebral column** (fig. 277) is a flexuous and flexible column, of a series of bones called *vertebræ*, which are united to one another by vertebral fibrocartilages. The bones are thirty-three in number, a grouped under the names *cervical*, *thoracic*, *lumbar*, *sacral*, and *co* according to the regions they occupy; there are seven cervical ve twelve thoracic, five lumbar, five sacral, and four coccygeal.

The cervical, thoracic, and lumbar vertebræ are separate bones thro life, and are therefore known as *movable* vertebræ; the sacral and co vertebræ, on the other hand, are termed *fixed* vertebræ, because th united in the adult to form two bones, viz. the *sacrum* and *coccyx*, respectively by the fused sacral and coccygeal vertebræ.

The General Characteristics of a Vertebra

With the exception of the first and second cervical, the movable ve have certain common characteristics which are best studied by exa one from the middle of the thoracic region.

A typical **vertebra** (fig. 246) consists of two principal parts, an a the *body*, and a posterior, the *vertebral arch*; these enclose a forame *vertebral foramen*.

In the articulated vertebral column the bodies form a pillar for the su of the head and trunk, and the vertebral foramina constitute a canal in the medulla spinalis or spinal cord is lodged and protected. Between pair of vertebræ are two *intervertebral foramina*, one on either side, transmission of the spinal nerves and vessels.

The **body** of a vertebra is more or less cylindrical in shape; its and lower surfaces are flattened and rough, and give attachment to the vertebral fibrocartilages, and each presents a rim around its circumf In front, it is convex from side to side and concave from above down behind, it is slightly concave from side to side and flat from above down On its anterior surface are a few small apertures for the passage of n vessels; on its posterior surface is a large, irregular aperture (occasi more than one) for the exit of the basivertebral veins from the body vertebra.

The **vertebral arch** consists of a pair of *pedicles* or *roots* and a p *laminæ*; it supports seven *processes*, viz. four *articular*, two *transverse* a *spinous*.

The *pedicles* or *roots of the vertebral arches*, are two short, thick proc which project backwards from the body, at the junctions of its latera

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

erior surfaces. The concavities above and below the pedicles are named *vertebral notches*; and when the vertebræ are articulated with one another, notches of contiguous pairs form the *intervertebral foramina*, already rred to.

The *laminæ* are two broad plates directed backwards and medialwards m the pedicles. They fuse in the middle line posteriorly, and so complete

FIG. 246.—A typical thoracic vertebra. Superior aspect.

posterior boundary of the vertebral foramen. Their upper borders and lower parts of their anterior surfaces are rough for the attachment of the menta flava.

The *spinous process* is directed backwards and downwards from the junction he laminæ, and serves for the attachment of muscles and ligaments.

The *articular processes*, two superior and two inferior, spring from the ctions of the pedicles and laminæ. The superior processes project upwards, l their articular surfaces are directed more or less backwards; the inferior ject downwards, and their articular surfaces look more or less forwards.

The *transverse processes* project lateralwards from the junctions of the icles and laminæ; y serve for the attach- t of muscles and ments.

tructure of a vertebra 247).—The body of a ebra is composed of gy substance covered a thin coating of com- bone; the latter is orated by numerous ces for the passage of sels; the interior of the y is traversed by one or large canals, for the ption of veins, which verge towards the large rture on the posterior surface of the body. The vertebral arch and the processes ecting from it have thick coverings of compact substance.

FIG. 247.—A sagittal section through a lumbar vertebra.

THE CERVICAL VERTEBRÆ (VERTEBRÆ CERVICALES)

The cervical vertebræ (figs. 248, 249), seven in number, are the smallest he movable vertebræ, and can be readily distinguished from the thoracic or bar vertebræ by the presence of a foramen in each transverse process.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The first, second, and seventh cervical vertebræ present exceptional f but the following characteristics are common to the remaining four.

The *body* is small, and broader from side to side than from before bac The anterior and posterior surfaces are flattened and of equal depth, anterior surface is placed on a lower level than the posterior, and its border is prolonged downwards, so as to overlap the upper and front pa succeeding vertebra. The superior surface is concave transversely, and

FIG. 248.—A typical cervical vertebra. Superior aspect.

upwardly projecting lip on either side; the inferior surface is saddle-s being concave from before backwards, convex from side to side, and p laterally shallow concavities which receive the projecting lips of the sub vertebra. The *pedicles* are directed lateralwards and backwards; th attached to the body midway between its upper and lower borders, and th the superior and inferior vertebral notches are of equal depth; the su notch is, however, the narrower. The *laminæ* are narrow, and are thinner than below; the *vertebral foramen* is large, and of triangular form *spinous process* is short and bifid, and its terminal tubercles are often of u size. The *superior and inferior articular processes* of either side are fused t an articular pillar, which projects lateralwards from the junction of the p and lamina. The articular facets are flat and of an oval form; the su

FIG. 249.—A typical cervical vertebra. Left lateral aspect.

facets look backwards, upwards, and slightly medialwards; the inferior for downwards, and slightly lateralwards. In the third and fourth ver the lateral surfaces of the articular pillars are grooved for the acco dation of the medial branches of the posterior divisions of the corres ing cervical nerves.* The *transverse processes* are each pierced by *foramen transversarium*, which, in the upper six vertebræ, gives pass the vertebral artery and vein and a plexus of sympathetic nerves.

* F. Wood Jones, *Journal of Anatomy and Physiology*, vol. xlvi., 1911.

ocess consists of an anterior and a posterior part. The anterior portion is homologue of the rib in the thoracic region, and is therefore named the *ral process*; it arises from the side of the body, is directed lateralwards in nt of the foramen, and ends in a tubercle, the *tuberculum anterius*. The terior part, the true transverse process, springs from the vertebral arch hind the foramen transversarium, and is directed forwards and lateralwards; ends in a flattened vertical tubercle, the *tuberculum posterius*. Lateral to e foramen transversarium the anterior and posterior tubercles are united by curved bar of bone, the groove or sulcus on the upper surface of which commodates the anterior division of the corresponding spinal nerve. This cus is deeper, wider, and more downwardly directed in the fifth and sixth n in the third and fourth vertebræ.*

Chassaignac pointed out that the common carotid artery can be compressed against anterior tubercle of the transverse process of the sixth cervical vertebra; this tubercle refore is named the *tuberculum caroticum* or *Chassaignac's tubercle*. It also contutes an important guide to the vertebral artery.

The **first cervical vertebra** (fig. 250) is named the **atlas** because it ports the globe of the head. Its chief peculiarity is that it has no body, and

FIG. 250.—The first cervical vertebra, or atlas. Superior aspect.

s is due to the fact that the body of the atlas has fused with that of the second vical vertebra. It has no spinous process but is ring-like, and consists of an erior and a posterior arch and two lateral masses. The *anterior arch* forms ut one-fifth of the ring: its front surface is convex, and at its centre is the *erior tubercle* for the attachment of parts of the Longus colli muscles; steriorly it is concave, and marked by a smooth, oval or circular facet (fovea ntis), for articulation with the anterior surface of the dens or odontoid process the epistropheus or axis. The upper and lower borders respectively give achment to the anterior atlanto-occipital membrane and the anterior atlanto-istropheal ligament; the former connects the atlas with the occipital bone, the ter the atlas with the epistropheus. The *posterior arch* forms about two-fifths the ring: at the centre of its posterior surface is the *posterior tubercle*, which the rudiment of a spinous process and gives origin to the Recti capitis steriores minores. The small size of this process prevents it from interfering th the movements between the atlas and the skull. The upper edge of the ntral part of the posterior arch is rounded and affords attachment to the sterior atlanto-occipital membrane, while immediately behind the superior icular process of each lateral mass is a groove, the *sulcus arteriæ vertebralis*, metimes converted into a foramen by a bony spiculum which arches backwards m the posterior end of the superior articular process. This sulcus lodges

* The *costal element* of a cervical vertebra not only includes the portion which springs from side of the body, but the anterior and posterior tubercles and the bar of bone which connects se tubercles (fig. 108).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the vertebral artery which, after ascending through the foramen in the tra process of the atlas, winds round the lateral mass in a direction bac and medialwards; it also lodges the suboccipital or first spinal nerv the under surface of the posterior arch, behind the inferior articular are the two shallow vertebral notches. The lower border of the po arch gives attachment to the posterior atlanto-epistropheal ligament.

The *lateral masses* support the weight of the head; each contributes one-fifth of the ring, and carries two articular facets, a superior and an i The superior articular facets are large, oval, and concave; they ap each other in front, but diverge behind; they are directed upwards, u wards, and a little backwards, and form cups for the reception of the co of the occipital bone, and are admirably adapted to the nodding move of the head; occasionally they are constricted near their centres. Just the medial margin of each superior facet is a small tubercle, for the attac of the transverse ligament of the atlas; this ligament divides the ring atlas into two unequal parts—the anterior, smaller part receiving the or odontoid process of the epistropheus, the posterior transmitting the m spinalis and its membranes. The inferior articular facets, nearly ci in form, are flattened or slightly concave; they are directed downward medialwards, and articulate with the superior facets of the epistrop The *transverse processes* are long and project lateralwards and downw from the lateral masses; the anterior and posterior tubercles of each pr are fused into one mass. The foramen transversarium is large and is di upwards and backwards.

The **second cervical vertebra** or **epistropheus** (axis) (figs. 251, forms the pivot upon which the atlas, carrying the head, rotates. The characteristic of this is the strong tooth process, the *dens*, projects perpendic from the upper surf the body. The *bo* deeper in front behind. On its an surface is a median r separating two d sions for the attach of portions of the L colli muscles. Its in surface is concave before backwards convex from side to The *dens* (odontoid cess), conical in shap about 1·5 cm. long, exhibits a slight cons tion, or neck, wher joins the body. O anterior surface is oval or nearly cir facet for articulation

FIG. 251.—The second cervical vertebra, or epistropheus. Posterosuperior aspect.

that on the posterior surface of the anterior arch of the atlas. On the ba the neck, and frequently extending on to its lateral surfaces, is a shallow gr for the transverse ligament of the atlas, which retains the dens in position. apex is pointed, and gives attachment to the ligamentum apicis dentis; b the apex, the process is somewhat enlarged and presents on either side a r impression for the attachment of the alar ligaments which connect the to the occipital bone. The internal structure of the dens is more compact that of the body. The *pedicles* are broad and strong, especially in front, w they fuse with the sides of the body and the base of the dens. They are co above by the superior articular surfaces. The *laminæ* are thick and str and the *vertebral foramen* is large, but smaller than that of the atlas. *transverse processes* are very small; each ends in a single tubercle a

forated by the foramen transversarium which is directed upwards and lateral-
ds. The *superior articular surfaces* are circular, slightly convex, directed
wards and a little lateralwards, and are supported on the body, pedicles, and
sverse processes; the *inferior* have the same direction as those of the typical
ical vertebræ. The *superior vertebral notches* are very shallow, and lie

FIG. 252.—The second cervical vertebra, or epistropheus. Right lateral aspect.

ind the articular processes; the *inferior* are in front of the articular processes,
in the typical cervical vertebræ. The *spinous process* is large and very
ong; it is deeply channelled on its under surface, and has a bifid, tuberculated
remity.

The **seventh cervical vertebra** (fig. 253).—This vertebra is named the
ebra prominens because of its long and prominent spinous process. This
cess is thick, and nearly horizontal in direction; it is not bifurcated, but
s in a tubercle to which the lower end of the ligamentum nuchæ is attached.

e *transverse processes* are
considerable size, and
ir posterior roots are
ge and prominent; the
erior roots are usually
ll and faintly marked,
occasionally they exist
separate bones, which
nd lateralwards and
wards, and are known
cervical ribs. The upper
face of each transverse
cess has usually a shal-
y sulcus for the seventh
vical nerve, and the

The Thoracic Vertebræ (Vertebræ Thoracales)

The **thoracic vertebræ** (fig. 254), twelve in number, increase succ in size from above downwards. All are distinguished by the presence o on the sides of the bodies, and all but the two lowest by facets on the tr processes; the former articulate with the heads of the ribs, the latter tubercles of the ribs.

The *first*, *ninth*, *tenth*, *eleventh*, and *twelfth* thoracic vertebræ present peculiarities, and must be specially considered (fig. 255).

In a typical vertebra from the middle of the thoracic region the heart-shaped, and its anteroposterior and transverse diameters are equal. It is slightly thicker behind than in front, flat above and below, from side to side in front, deeply concave behind, and slightly con laterally and in front. On either side are two costal facets, a superi

Fig. 254.—A typical thoracic vertebra. Right lateral aspect.

larger, near the root of the pedicle, and an inferior in front of the in vertebral notch; in the articulated vertebral column these facets form the intervertebral fibrocartilages, oval surfaces for the reception of the of the ribs. The *pedicles* are directed backwards and slightly upwards the inferior vertebral notches are of large size, and deeper than those cervical or lumbar vertebræ. The *laminæ* are broad and thick, and ov those of subjacent vertebræ like tiles on a roof. The *vertebral foramen* is sm than that of a cervical or lumbar vertebra, and is of a circular form. *spinous process* is long, triangular on coronal section, directed obliquely wards, and ends in a tuberculated extremity. The spinous processes ov from the fifth to the eighth, but are less oblique in direction above and these levels.* The *superior articular processes* are thin plates of bone proj upwards from the junctions of the pedicles and laminæ; their articular are almost flat, and are directed backwards and a little lateralwards and up The *inferior articular processes* are fused to a considerable extent wit laminæ, and project but slightly beyond the lower borders of the la their facets are directed forwards and a little medialwards and down

* In quadrupeds the majority of the spinous processes of the thoracic vertebræ upwards and backwards, while those of the lumbar region are directed upwards and for The change in inclination is effected in one of the lower thoracic vertebræ, the spine of points almost directly upwards. This vertebra is known as the *anticlinal*, and in m representative is the eleventh thoracic.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

e *transverse processes* arise from the arch behind the superior articular pro-
sses and pedicles; they are thick, strong, and of considerable length, directed
liquely backwards and lateralwards, and each ends in a clubbed extremity,
the front of which is a small costal facet, for articulation with the tubercle
a rib. In the upper six thoracic vertebræ the costal facets are concave,

FIG. 255.—The first, ninth, tenth, eleventh and twelfth thoracic vertebræ. Right lateral aspect.

d are placed on the anterior surfaces of the transverse processes; in the
rtebræ from the seventh to the tenth inclusive the costal facets are flat and
aced on the upper surfaces of the transverse processes.

The **first thoracic vertebra** (fig. 255) has on either side of the upper part
the body a complete facet for the head of the first rib, and at the lower part
the body a small facet for the upper half of the head of the second rib. The
dy resembles that of the seventh cervical vertebra, being broad transversely,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

while its upper surface is concave in the same direction, and lipped on side. The *superior articular surfaces* are directed upwards and back the *spinous process* is thick, long, and almost horizontal. The *tra processes* are long, and the superior vertebral notches are deeper than of the other thoracic vertebræ.

The **ninth thoracic vertebra** (fig. 255) may have no inferior costal but in some cases these are present.

The **tenth thoracic vertebra** (fig. 255) has usually a complete costal placed partly on the lateral surface of the pedicle, for the head of the ten but the facet for the head of this rib is sometimes completed by the body ninth vertebra.

In the **eleventh thoracic vertebra** (fig. 255) the *body* approaches in and size those of the lumbar vertebræ. The facets for the heads of the el pair of ribs are large, and placed chiefly on the pedicles, which are thick stronger in this and the next vertebra than in other parts of the thoracic r The *spinous process* is short, and nearly horizontal in direction. The *tra processes* are very short, tuberculated at their extremities, and have no facets.

The **twelfth thoracic vertebra** (fig. 255) has the same general ch teristics as the eleventh, but may be distinguished from it by its inferior art surfaces which are convex and directed lateralwards like those of the lum vertebræ; by the body, laminæ, and spinous process, which resemble tho the lumbar vertebræ; and by each transverse process being a short irre knob subdivided into superior, inferior, and lateral tubercles; the su and inferior tubercles correspond to the mamillary and accessory pro of the lumbar vertebræ. Traces of similar tubercles are found on the tran processes of the tenth and eleventh thoracic vertebræ.

The Lumbar Vertebræ (Vertebræ Lumbales)

The **lumbar vertebræ** (figs. 256, 257), five in number, are the l of the movable vertebræ, and can be distinguished by the absence of for in their transverse processes, and of costal facets on the sides of the bodi

Fig. 256.—A lumbar vertebra. Right lateral aspect.

The *body* is large, wider from side to side than from before backwards a little thicker in front than behind. It is flattened above and below, con behind, and constricted in front and at the sides. The *pedicles* are strong directed backwards from the upper part of the body; consequently, the inf vertebral notches are of considerable depth. The *laminæ* are broad, sh and strong; the *vertebral foramen* is triangular, larger than in the thoracic smaller than in the cervical region. The *spinous process* projects al

backwards and medialwards; those on the lumbar convex, and are d
forwards and lateralwards. The inferior articular processes are closer t
than the superior, and, in the articulated vertebral column, are embra
the superior processes of the subjacent vertebra. The *transverse proce*
situated in front of the articular processes instead of behind them as
thoracic vertebræ, and are homologous with the ribs. Those of the uppe
vertebræ arise from the junctions of the pedicles and laminæ, and ar
slender, and horizontally directed; those of the lower two vertebræ
a little upwards, and spring from the pedicles and posterior parts of the
The transverse process of the first lumbar vertebra is sometimes dev
as a separate piece which may remain ununited with the rest of the
thus forming a lumbar rib. Of the tubercles noticed in connexion wi
transverse processes of the lower thoracic vertebræ, the *superior* is com
in the lumbar region with the posterior part of the superior articular p
and is named the *mamillary process;* the *inferior* is situated at the po
part of the base of the transverse process, and is called the *accessory p*
(fig. 257).*

The **fifth lumbar vertebra** (fig. 258) is characterised by its body
considerably deeper in front than behind, a condition which accords wi
prominence of the sacrovertebral articulation; by the small size of its sp
process; by the wide interval between the inferior articular processes;
by the thickness of its transverse processes, which spring from the bod
well as from the pedicles.

The Sacrum (Os Sacrum)

The **sacrum** is a large, wedge-shaped bone formed by the fusion of th
sacral vertebræ. It is situated at the upper and posterior part of the
cavity, where it is inserted like a wedge between the two hip-bones
base projects upwards and forwards to articulate with the fifth lumbar ve
and form with it the prominent *sacrovertebral angle*; its apex articulates
the coccyx. The bone is placed very obliquely and is curved longitud
with a dorsal convexity, so that its central part is projected upward
backwards to give increased capacity to the cavity of the lesser pelvis.
sides of the wedge are somewhat sinuous in outline since the third sacral ve
is rather wider than the second. The sacrum has a pelvic, a dorsal, and
lateral surfaces, a base, an apex, and a central canal.

The *pelvic surface* of the sacrum (fig. 259) is concave from above down
and slightly so from side to side. It is crossed transversely by four ridges,
correspond in position with the original planes of separation between th
segments of the bone: the portions separated by the ridges are the bodies
sacral vertebræ. The body of the first vertebra is of large size, and in
resembles that of a lumbar vertebra; the succeeding ones diminish from
downwards, are flattened from before backwards, and curved to accomm
themselves to the form of the sacrum, being concave in front, and co
behind. On either side, at the ends of the ridges are the four *anterior*
foramina, somewhat rounded in form, diminishing successively in size
above downwards, and directed lateralwards and forwards: they open
the sacral canal and give exit to the anterior divisions of the sacral ne
and entrance to the lateral sacral arteries. On either side of these fora
are the *lateral parts* of the sacrum, each consisting of five separate segm
at an early period of life; in the adult, these are blended with the bodies
with each other. Each lateral part is traversed by four broad, shallow gro
for the anterior divisions of the sacral nerves; the grooves are separ
from one another by prominent ridges which give origin to the Piriformis.

In a medial sagittal section of the sacrum (fig. 263) the central par
the bodies of the sacral vertebræ are seen to be separated by intervals w

* The mamillary and accessory processes 'are merely muscular processes which, repre
and conjoined in the thoracic region, become separated in the lumbar region by the p
of the internal branch of the posterior division of the lower thoracic and lumbar nerves be
them.' (Wood Jones, *Journal of Anatomy and Physiology*, vol. lvii., p. 118.)

the recent state, are filled by the intervertebral fibrocartilages. In some cimens the union is more complete between the lower than between the er segments.

The *dorsal surface* of the sacrum (fig. 260) is convex, and is narrower than pelvic surface. In the middle line is the *median sacral crest*, surmounted the rudimentary spinous processes of the upper three or four sacral vertebræ. either side of this crest is the *sacral groove*, which gives origin to the tifidus, the floor of the groove being formed by the united laminæ of the tebræ. The laminæ of the fifth sacral vertebra, and sometimes those of fourth, fail to meet behind, and thus a deficiency (*hiatus sacralis*) occurs in posterior wall of the sacral canal. Lateral to either sacral groove is a linear

FIG. 259.—The sacrum. Pelvic aspect.

es of tubercles produced by the fusion of the articular processes, which ether form the indistinct *sacral articular crests*. The articular processes of first sacral vertebra are large, and their facets are oval or circular in shape, concave from side to side; they look backwards and medialwards, and iculate with the facets on the inferior processes of the fifth lumbar vertebra. e tubercles which represent the inferior articular processes of the fifth sacral tebra are prolonged downwards as rounded processes, which are named *sacral cornua*, and are connected to the cornua of the coccyx. Lateral the sacral articular crests are the four *posterior sacral foramina*; they transmit posterior divisions of the sacral nerves, and are smaller in size and less ular in form than the anterior foramina. Lateral to the posterior sacral mina are the *lateral sacral crests*, formed by the fused transverse processes the sacral vertebræ. The transverse tubercles of the first sacral vertebra large and very distinct; they and the transverse tubercles of the second tebra, give attachment to the short posterior sacro-iliac ligaments; those of third vertebra give attachment to the long posterior sacro-iliac ligaments; those of the fourth and fifth to the sacrotuberous ligaments.

The *lateral surfaces* of the sacrum (fig. 260) are broad above, and below. On the broad upper part of each is an ear-shaped surface, the *surface*, for articulation with the ilium, and behind this is a rough *sacral tuberosity*, on which are three deep impressions, for the att of the interosseous sacro-iliac ligament; the thin, lower part gives att to the sacrotuberous and sacrospinous ligaments, to some fibres of the maximus behind, and of the Coccygeus in front. It ends below in a p called the *inferior lateral angle*; the notch on the medial side of th is converted into a foramen by the transverse process of the first piec coccyx, and transmits the anterior division of the fifth sacral nerve.

Fig. 260.—The sacrum. Dorsal aspect.

The *base* of the sacrum (fig. 262) is transversely expanded, and is dir upwards and forwards. In its central part is the large oval upper surf the body of the first sacral vertebra, which is connected with the under s of the body of the last lumbar vertebra by an intervertebral fibrocart the anterior projecting edge of the body is named the *promontory*. Behi body is the superior orifice of the sacral canal, triangular in shape and com posteriorly by the arch of the first sacral vertebra. On either side of the is a large triangular plate called the *ala sacralis*. The upper surface of t is slightly concave from side to side, and convex from before backward in the articulated pelvis is continuous with the iliac fossa. The po one-third of the ala represents the transverse process, and the anterior two- the costal process of the first sacral vertebra. The superior articular pro are attached to the body of the first sacral vertebra and to the alæ by thick pedicles; they are oval, concave, directed backwards and medial like the superior articular processes of the lumbar vertebræ. On the surface of either pedicle is a vertebral notch, which forms the lower p the foramen between the last lumbar and first sacral vertebræ.

The *apex* of the sacrum, directed downwards, is truncated and an oval facet for articulation with the coccyx.

The *sacral canal* (fig. 263) lodges the sacral nerves and runs thro greater part of the length of the bone; above, it is a closed canal, tri in cross section; below, its posterior wall is incomplete, owing to th development of the laminæ and spinous processes. Its walls are per by the anterior and posterior sacral foramina through which the emerge.

Differences in the sacrum of the male and female.—In the the sacrum is shorter and wider than in the male; the upper part of th is flattened, and the lower part curved abruptly forwards. In the m

Fig. 263.—A median sagittal section through the sacrum.

curvature is more evenly distributed over the whole length of the bone the female the bone is directed more obliquely backwards than in the m this increases the size of the pelvic cavity and renders the sacrovertebral more prominent. In the female the auricular surface for articulation the ilium is shorter than that in the male, extending along the sides o first and second sacral vertebræ only; in the male it is continued down t middle or lower limit of the third vertebra.

Structure.—The sacrum consists of spongy substance enveloped by a thin of compact bone.

Variations.—The curvature of the sacrum varies considerably in dif specimens of the same sex. In some cases the bone consists of six vertebr others of four. The transverse process of the first sacral segment may n joined to the rest of the ala on one or both sides, and a considerable part o posterior wall of the sacral canal may be wanting, in consequence of the imp development of the laminæ and spinous processes.

THE COCCYX (OS COCCYGIS)

he **coccyx** (figs. 264, 265) is a small, triangular bone consisting usually of rudimentary vertebræ, but the number may be increased to five or reduced ce; it forms a pointed apex for the sacral wedge.

he *first coccygeal vertebra* is the largest and often exists as a separate piece. he upper surface of its central part or body, is an oval facet for articulation the apex of the sacrum. Two processes, named *coccygeal cornua*, project rds from the posterolateral parts of the body; they are the homologues e pedicles and superior articular processes of the movable vertebræ. They d to articulate with the sacral cornua, and, on either side, form part e margin of the intervertebral foramen for the fifth sacral nerve. A entary transverse process projects lateralwards and slightly upwards either side of the body. It is flattened from before backwards, and ascends to articulate with the inferior lateral angle of the sacrum, thus leting the foramen for the passage of the anterior division of the fifth l nerve; the posterior division of this nerve descends on the back of the verse process.

64.—The coccyx. Anterior aspect.

FIG. 265.—The coccyx. Posterior aspect.

he *second*, *third*, and *fourth coccygeal vertebræ* diminish successively in size, are usually fused with one another. The second shows traces of transverse esses and pedicles; the third and fourth represent only rudimentary ebral bodies, and are mere nodules of bone.

he filum terminale of the medulla spinalis is attached to the posterior ce of the first segment. The Glutæus maximus arises from the posterior aces of the first three segments, and the Sphincter ani externus from the The Coccygei and Levatores ani are attached to the thin lateral edges, to the adjoining parts of the anterior surface of the bone.

The ossification of the vertebral column.—Each typical vertebra is ossified from e primary centres (fig. 266), two for the vertebral arch, and one for the body.* fication of the vertebral arches begins in the upper cervical vertebræ about the nth or eighth week of fœtal life, and gradually extends down the column. The res first appear in the situations where the transverse processes afterwards ect, and spread backwards to the spinous process, forwards into the pedicles, lateralwards into the transverse processes. Ossification of the bodies begins he lower thoracic vertebræ about the eighth week of fœtal life, and subsequently nds upwards and downwards along the column. The centre for the body does give rise to the whole of the body of the adult vertebra, the posterolateral portions which are ossified from the centres for the vertebral arch. The body of a ebra during the first few years of life shows, therefore, two synchondroses *rocentral synchondroses*) traversing it along the planes of junction of these three res (fig. 267). In the thoracic region the costal facets on the bodies lie behind neurocentral synchondroses. At birth a vertebra consists of three pieces, viz. the y and the halves of the vertebral arch. During the first year the halves of the

* The body is occasionally ossified from two lateral centres which sometimes fail to unite.

es, and the body from one, as in a typical vertebra; the centres for the arch r about the seventh or eighth week of fœtal life, the centre for the body about fourth or fifth month. The dens or oid process represents the body of the and is chiefly ossified from two later- laced centres; these appear about the month of fœtal life, and join before to form a conical mass, deeply cleft e. A wedge-shaped piece of cartilage he cleft and forms the summit of the ss; in this cartilage a centre appears t the second year and unites with the mass of the dens about the twelfth year. base of the dens is separated from the of the epistropheus by a cartilaginous the circumference of which ossifies, but entre remains cartilaginous until ad- d age; in this cartilaginous disc, ents of the lower epiphysial lamella of plas and the upper epiphysial lamella epistropheus may sometimes be found. dition to these centres there is one for n epiphysial plate on the under surface e body of the bone.

he **seventh cervical vertebra.**—The l processes of this vertebra are usually ed from separate centres which appear t the sixth month of fœtal life, and the body and transverse processes een the fifth and sixth years. As dy stated (p. 169), the costal processes persist as separate pieces, and grow lwards and forwards, to constitute ical ribs.

Separate ossific centres have also been d in the costal processes of the fourth, and sixth cervical vertebræ.

The **lumbar vertebræ** (fig. 271) have each additional centres, for the mamillary esses.

he **sacrum** (figs. 272 to 275).—Each i vertebra is ossified from three primary es, one for the body and two for the ebral arch. Two epiphysial plates are ed for each body, one for the upper and other for the lower surface.

The anterior portions of the lateral parts he sacrum have six additional (costal) es, two for each of the first three verte- ; these appear above and lateral to the erior sacral foramina (figs. 272, 273).

Two epiphysial plates are developed on er lateral surface of the sacrum (figs. 274,); one for the auricular surface, and ther for the thin edge of bone below surface.

FIG. 272.—The ossification of the sacrum and coccyx.

FIG. 273.

FIG. 274.

The two epiphysial plates for each lateral surface are marked by asterisks.

FIG. 275.—The base of the sacrum of an adolescent.

The ends of the spinous processes of the upper three sacral vertebræ are some- s developed from separate epiphyses, and Fawcett* has pointed out that a ber of epiphyses are present in the sacrum at the eighteenth year (fig. 276). se are distributed as follows: One for each of the two mamillary processes of first sacral vertebra; twelve, six on either side, in connexion with the costal esses (two each—an anterior and a posterior—for the first and second, and

one each—an anterior—for the third and fourth vertebræ; and eight, four side, for the transverse processes, one each for the first, third, fourth He is also of opinion (1) that the auricular facets on the lateral surfaces of th are in the main formed by the development and fusion of the costal epiphy first and second sacral vertebræ, and (2) that the lower part of each lateral formed by the extension and union of the costal epiphyses of the third a with the epiphyses of the transverse processes of the fourth and fifth, sacral

The periods of ossification of the sacrum.—The centres for the bodi first, second and third sacral vertebræ appear towards the end of the thir and those for the bodies of th and fifth vertebræ between and eighth months of fo The centres for the vertebr appear about the fifth mon those for the costal proc the lateral parts of the bone the sixth and eighth months life. In the lower vertel arches fuse with the bodies second year; in the first fusion does not occur until th or sixth year. About the si year the epiphysial plates upper and under surfaces bodies are formed; and betw eighteenth and twentieth year for the lateral surfaces of th make their appearance. Duri life, the bodies of the sacral are separated from each o intervertebral fibrocartilages, b the eighteenth year the bodie two lower vertebræ become united by bone, and the process of bon gradually extends upwards, with the result that between the twenty-f thirtieth years of life all the vertebræ are united (fig. 263).

Fig. 276.—The epiphyses of the costal and transverse processes of the sacrum at the eighteenth year. (E. Fawcett.)

A.C. 1, 2, 3, 4, Anterior epiphyses for first, second, third and fourth costal processes. *P.C.* 1, 2, Posterior epiphyses for first and second costal processes. *T.* 1, 3, 4, 5, Epiphyses for the first, third, fourth and fifth transverse processes.

The **coccyx.**—Each segment of the coccyx is ossified from one centr centres appear in the following order: in the first segment between the f fourth years; in the second between the fifth and tenth years; in the third the tenth and fifteenth years; in the fourth between the fourteenth and tw years. A secondary centre for each coccygeal cornu, and a pair of epiphysi for each of the rudimentary bodies have been described. As age advan segments unite with one another, the union between the first and secon frequently delayed until after the age of twenty-five or thirty years. A period of life, especially in females, the coccyx often fuses with the sacrum.

The Vertebral Column as a Whole

The **vertebral column** is situated in the median line. at the p part of the trunk. Its average length in the male is about 71 cm.; the cervical part measures 12·5 cm., the thoracic 28 cm., the lumbar and the sacrum and coccyx 12·5 cm. The average length of the female v column is about 61 cm.

The curves of the vertebral column.—Viewed laterally (fig. 277), the v column presents cervical, thoracic, lumbar, and pelvic curves. The and pelvic curves are termed primary curves, because they alone are during fœtal life. The cervical and lumbar curves are secondary or co tory, and are developed after birth, the cervical curve when the child to hold up its head (at three or four months), and to sit upright (abo months), the lumbar at twelve or eighteen months when the child b walk. The *cervical* curve is convex forwards, and is the least marked four; it begins at the atlas, and ends at the middle of the second vertebra. The *thoracic* curve is concave forwards, and extends fr

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

dle of the second to the middle of twelfth thoracic vertebra. The *bar* curve is convex anteriorly is more pronounced in the female in the male; it reaches from the dle of the last thoracic vertebra he sacrovertebral angle, and the vexity of the lower three segments reater than that of the upper two. *pelvic* curve extends from the overtebral articulation to the of the coccyx; its concavity is cted downwards and forwards.

In the upper part of the thoracic on of the vertebral column e is a slight *lateral* curvature, its convexity directed towards right side in right-handed per-

Some regard this curve as due to the greater use and ularity of the right arm, and in ort of this explanation it has found that in left-handed viduals the convexity of the e is directed towards the left

Others regard it as being uced by the aortic arch and er part of the descending thoracic a—a view which is supported the fact that in cases where the era are transposed and the a is consequently on the right the convexity of the curve is cted to the left.

The *anterior surface* of the verte- column.—When viewed from ront, the width of the bodies of vertebræ is seen to increase n the second cervical to the first acic; there is then a slight inution in the next three verte- ; below this there is again a ual and progressive increase in h as low as the sacrovertebral e. From this level there is a d diminution, to the apex of the yx.

The *posterior surface* of the ebral column presents in the ian line the spinous processes. the cervical region (with the ption of the second and seventh ebræ) these are short and hori- tal, with bifid ends. In the upper of the thoracic region they are cted obliquely downwards; in middle part they are long and ost vertical; in the lower part he thoracic region and in the bar region they are nearly hori- tal. They are separated by con- rable intervals in the cervical lumbar regions, but are closely

FIG. 277.—The vertebral column. Left lateral aspect.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

approximated in the middle of the thoracic region. Occasionally a process may deviate from the median line—a fact to be remembered in as irregularities of this sort are attendant also on fractures or displ of the vertebral column. At the sides of the spinous processes *vertebral grooves* which lodge the deep muscles of the back. In the and lumbar regions these grooves are shallow and are formed by the of the vertebræ; in the thoracic region they are deep and wide, formed by the laminæ and transverse processes. Lateral to the grooves are the articular processes, and still more lateral the transve cesses. In the thoracic region, the transverse processes stand backwar plane considerably behind that of the same processes in the cervical and regions. In the cervical region, the transverse processes are placed of the articular processes, lateral to the pedicles, and between the interv foramina. In the thoracic region they are behind the pedicles, interv foramina, and articular processes. In the lumbar region they are in the articular processes, but behind the intervertebral foramina.

The *lateral surfaces* of the vertebral column are separated from the surface by the articular processes in the cervical and lumbar regions, the transverse processes in the thoracic region. In front are the sides bodies of the vertebræ, marked in the thoracic region by the facets for a tion with the heads of the ribs. Between the pedicles are the interver foramina, oval in shape, smallest in the cervical and upper part of the th regions, and gradually increasing in size to the last lumbar; these fo transmit the spinal nerves and vessels.

The *vertebral canal* follows the curves of the column; it is large and tri in the cervical and lumbar regions, where movement is free, but sm circular in the thoracic region, where motion is more limited.

Applied Anatomy.—Occasionally the coalescence of the laminæ is not comple consequently a cleft is left in the arches of the vertebræ, through which a prot the spinal membranes (dura mater and arachnoid), and generally of the medulla and pia mater, takes place, constituting the malformation known as *spina bifi* condition is most common in the lumbosacral region, but it may occur in the or cervical region, or the arches throughout the whole length of the canal may incomplete.

Although there is only a very limited amount of movement between any t tiguous vertebræ, there is a considerable range of movement in the vertebral colu whole. The intervertebral fibrocartilages act as buffers between the different s and counteract or neutralize the effect of jars or shocks which may be applied column; for example, dropping from a height on to the feet rarely causes conc the brain or spinal medulla. The security of the column is also provided for by its tion in curves, enabling it to bend without breaking. The vertebræ are so firmly to one another that violence applied to the column is more likely to produce fr dislocation than a tearing of ligaments.

Fracture-dislocations of the vertebral column are more frequently caused by than by direct violence. When produced by indirect violence, the upper seg driven forwards on the lower, and the spinal medulla is compressed between the the vertebra immediately below, and the arch of the vertebra immediately ab injury. Since the spinal medulla ends at the level of the upper border of the lumbar vertebra it follows that partial dislocations, or gunshot wounds, below th are less serious than those above it.

The normal position of the vertebral column may be altered either by the form new curvatures or by an increase of some of the normal ones. In many cases, no rapidly growing adolescents, the deformity results from weakness of the supporting which are unable to keep the vertebræ firmly applied to one another, and altera the disposition of the column are produced by the weight of the body. In later persistent use of faulty positions (e.g. in shoemakers, tailors, etc.) or the carrying of suspended from the trunk (e.g. in hawkers) may distort the vertebral column. I cases the changes in the curvatures may be the result of diseases of the vertebræ ligaments (e.g. tuberculosis, rheumatism, etc.). Sometimes the deviations result m cally from the effects of disease in other parts (e.g. in cases of shortening of one hip-joint disease, or in cases of adhesions in the thorax from an old empyema). in the curvatures of the vertebral column are multiple since secondary (compe curves form to restore the balance of the body.

The chief forms of abnormal curvatures are scoliosis, kyphosis and lordosis. In the column is bent to one side, and this is accompanied by a rotation of the vertebral round a vertical axis. In *kyphosis* the thoracic curve is increased, while in *lord* deformity is an exaggeration of the lumbar curve.

aminectomy.—The operation of laminectomy is performed in cases of pressure on edulla spinalis, where the continuity of the nerve-tracts has not been completely yed. It consists of cutting down on and removing the laminæ and spinous pro- in the affected region, so as to relieve the medulla spinalis from pressure; but it less in cases of complete destruction of this structure. Laminectomy is chiefly med (i) for fracture-dislocation; (ii) for localised pressure in cases of spinal caries, ject here being to remove the laminæ against which the medulla spinalis is pressed e inflammatory mass, and (iii) for the removal of tumours growing inside the bral canal and compressing the medulla spinalis. If such cases be taken early, very actory results are obtained.

e subarachnoid cavity ends at the level of the lower border of the second sacral bra; the lower part of the sacrum may therefore be removed to expose growths or urs of the rectum without opening into this cavity.

The Sternum

e **sternum** (figs. 278 to 280) is a long flat bone, forming the middle on of the anterior wall of the thorax. Its average length is about 17 cm., s rather greater in the male than in the female. Its upper end supports lavicles, and its margins articulate with the cartilages of the first seven of ribs. It consists of three parts, named from above downwards, the *rium*, the *body*, and the *xiphoid process*; in early life the body consists r segments or *sternebræ*. In its natural position the inclination of the is oblique from above, downwards and forwards. It is slightly convex ont, and concave behind; it is broad above, narrow at the junction of manubrium with the body, below which it gradually widens as far as the of the articulations of the cartilages of the fifth ribs, and then narrows kly to its lower extremity.

e **manubrium sterni** is of a somewhat triangular form, broad and thick e, narrow below at its junction with the body. Its *anterior surface*, convex side to side, concave from above downwards, is smooth, and affords hment on either side to the sternal origins of the Pectoralis major and ocleidomastoideus. Its *posterior surface*, concave and smooth, gives n on either side to the Sternohyoideus and Sternothyreoideus. The *rior border* is thick, and presents at its centre the *jugular notch*; on either of this notch is an oval articular surface, directed upwards, backwards, and lwards, for articulation with the sternal end of the clavicle. The *inferior r*, oval and rough, is covered in the recent state with a thin layer of lage, for articulation with the upper end of the body. The *lateral borders* ach marked above by a depression for the reception of the first costal lage, and below by a small articular facet, which, with a similar one on pper angle of the body, forms a notch for the sternal end of the costal ge of the second rib. Between the depression for the first costal cartilage the facet for the second is a narrow, curved edge, which slopes from above wards and medialwards.

e **body** of the sternum, longer, narrower, and thinner than the manubrium, ns its greatest breadth close to the lower end. Its *anterior surface*, nearly is directed forwards and upwards, and is marked by three transverse s opposite the third, fourth, and fifth articular depressions.* It affords hment on either side to the sternal origin of the Pectoralis major. A *al foramen*, of varying size and form, is occasionally seen at the junction e third and fourth pieces of the body. The *posterior surface*, slightly ave, is also marked by three transverse lines, less distinct, however, than e on the anterior surface; from its lower part, on either side, the Transversus acis takes origin. The *upper end* is oval and articulates with the manu- n, the junction of the two forming the *sternal angle* (*angulus Ludovici* †). *lower end* is narrow, and articulates with the xiphoid process. Each *l border* (fig. 280), at its superior angle, has a small facet, which with a

Paterson (*The Human Sternum*, 1904) found that these ridges were absent in 26·7 per cent.; ridge existed opposite the third costal cartilage in 69 per cent.; opposite the fourth in cent.; and opposite the fifth in 4 per cent.

Named after the French surgeon Antoine Louis, 1723-1792. The Latin term *angulus ici* is not infrequently mistranslated into English as 'the angle of Ludwig.'

similar one on the manubrium, forms a notch for the reception of the end of the cartilage of the second rib; below this are four angular facets to receive the sternal ends of the cartilages of the third, fourth, fifth, and sixth ribs; the inferior angle has a small facet, which, with a similar one on the xiphoid process, forms a notch for the reception of the cartilage of the

FIG. 278.—The sternum and costal cartilages. Anterior aspect.

rib. These articular depressions are separated by a series of curved which diminish in length from above downwards, and correspond to the ends of the intercostal spaces.

It will be observed that most of the cartilages of the true ribs articulate sternum at the lines of junction of its primitive component segments; this is well many of the lower animals, where the parts of the bone remain ununited long in man.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **xiphoid process** is the smallest piece of the sternum; it is thin and gated, cartilaginous in youth, but more or less ossified at its upper part be adult. Its *anterior surface* affords attachment on either side to the rior costoxiphoid ligament and a small part of the Rectus abdominis; its rior *surface*, to the posterior costoxiphoid ligaments and to some of the s of the Diaphragm and Transversus thoracis; its *lateral borders*, to the euroses of the abdominal muscles. Above, it articulates with the lower of the body of the bone, and on the front of each superior angle is a facet part of the cartilage of the seventh rib; the linea alba is attached to its ted lower end.

The xiphoid process varies greatly; it may be broad and thin, pointed, perforated, curved, or deflected to one or other side.

279.—The sternum. Posterior aspect.

FIG. 280.—The sternum. Lateral aspect.

Structure.—The sternum is composed of highly vascular spongy substance red by a layer of compact bone which is thickest on the manubrium between articular facets for the clavicles.

Ossification.—The sternum originally consists of two cartilaginous *sternal es*, one on either side of the median plane. Opposite the first seven pairs of ribs e plates fuse with one another in the middle line to form the cartilaginous num, which is ossified from six centres: one for the manubrium, four for the y, and one for the xiphoid process (fig. 281). These centres appear in the rvals between the articular depressions for the costal cartilages, in the following r: in the manubrium and first piece of the body, during the sixth month of fœtal in the second and third pieces of the body, during the seventh month of fœtal in the fourth piece, shortly before birth; and in the xiphoid process, in the third or much later.* Two small episternal centres sometimes appear, one on either of the jugular notch; they are probably vestiges of the episternal bone of the otremata and lizards. The manubrium may have two, three, or more centres;

Paterson (*op. cit.*) found the fourth or lowest centre for the body present only in 26·9 per of cases.

Digitized by Arya Samaj Foundation Chennai and eGangotri

when two are present, one is generally situated above the other, the up the larger. The first segment of the body has seldom more than one cen the second, third, and fourth segments are often ossified from two lateral centres, and if these fail to join, the foramen or fissure which is occasion in this part of the bone results. Union between the centres of the bod about puberty, and proceeds from below upwards (fig. 282); by the age of five they are all united. The xiphoid process usually fuses with the bo

(vertebrochondral ribs); the eleventh and twelfth are free at their anterior and are termed *floating* or *vertebral* ribs.

FIG. 283.—A central rib of the left side. Inferior aspect.

The ribs are situated one below the other in such a manner that spaces, called *intercostal spaces*, are left between them. The length of each space corresponds to that of the adjacent ribs and their cartilages; the breadth is greater in front than behind, and between the upper than the lower ribs. The ribs vary in their direction, the upper ones being less oblique than the lower; the obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs increase in length from the first to the seventh, below which they diminish to the twelfth. In breadth they decrease successively from above downwards; in the upper ten the greatest breadth is at the anterior extremity.

Common characteristics of the ribs (figs. 283, 284).—A rib from the middle of the series should be taken in order to study the common characteristics of these bones.

Each rib has a posterior and an anterior extremity, and an intervening portion—the body or shaft.

The **posterior or vertebral end** presents for examination a head, neck, and tubercle.

On the *head* are two facets, a superior and an inferior, separated by a transverse crest or ridge named the *crista capituli*. The facets, of which the superior is the smaller, articulate with the bodies of two contiguous thoracic vertebræ, and the crista capituli is attached to the intervertebral fibrocartilage by the interarticular ligament.

The *neck* is the flattened portion which succeeds the head; it is about 2·5 cm. long, and is placed in front of the transverse process of the lower of the two vertebræ with which the head articulates. It is placed obliquely, so that its anterior surface looks forwards and upwards, and its posterior, backwards and downwards. Its *anterior surface* consists of an upper and a lower area separated by a ridge which affords attachment to the posterior intercostal membrane and is continuous with the inner lip of the superior border of the body or shaft. The upper area, of varying size and more or less triangular in shape, is separated from the erior intercostal membrane by some fatty tissue; the lower is smooth and red by the costal pleura. Its *posterior surface* is rough for the attachment

of the groove constitutes the *inferior border* of the rib, and gives attach- to an Intercostalis externus. The *superior border* of the rib, thick and ded, is marked by an external and an internal lip, more distinct behind in front; the former gives attachment to an Intercostalis externus, the to an Intercostalis internus.

the **anterior or sternal end** is an oval, cup-shaped depression, into the lateral end of the costal cartilage is received.

he first, second, tenth, eleventh, and twelfth ribs present certain variations, equire special consideration.

he **first rib** (fig. 285) is the most curved and usually the shortest of the it is broad and flat, its surfaces looking upwards and downwards, and orders inwards and outwards. The *head* is small, rounded, and has only gle, nearly circular, articular facet, which articulates with the upper of the side of the body of the first thoracic vertebra. The *neck* is

Fig. 285.—The first and second ribs. Superior aspect.

hat rounded. The *tubercle*, thick and prominent, is directed upwards backwards; on its medial part is an oval facet for articulation with the verse process of the first thoracic vertebra. At the tubercle the rib is so that the head of the bone is directed slightly downwards. There is gle. The *upper surface* of the body is marked by two shallow grooves, ated from one another by a slight ridge which ends at the inner border of b in the *scalene tubercle*. The tubercle gives the attachment of the Scalenus ior; the groove in front of it supports the subclavian vein, that behind e subclavian artery and the lowest trunk of the brachial plexus.* The ce in front of the anterior groove gives origin to the Subclavius muscle, attachment to the costoclavicular ligament; behind the posterior groove rough area for the attachment of the Scalenus medius. The *under sur-* is smooth, and destitute of a costal groove. The *outer border* is convex, behind, but thin in front. Immediately behind the subclavian groove es origin to the upper part of the first digitation of the Serratus anterior. *nner border* is concave and thin, and marked near its centre by the e tubercle. The *anterior end* is larger and thicker than that of any of her ribs.

he **second rib** (fig. 285) is about twice the length of the first, but has ilar curvature. The non-articular portion of the *tubercle* is often small.

*See article by Wood Jones, *Anat. Anzeiger*, Bd. xxxvi, 1910.

The *angle* is slight, and situated close to the tubercle. The *body* is no so that both ends of it touch any plane surface upon which the rib may but at the tubercle there is an upward convexity, similar to, but sma that found in the first rib. The *external surface* of the body is convex, upwards and a little outwards; near its middle is a rough eminenc origin of the lower part of the first and the whole of the second of the Serratus anterior; behind and above this the Scalenus po inserted. The *internal surface*, smooth and concave, is directed do and a little inwards; on its posterior part there is a short costal groo

The **tenth rib** (fig. 286) has only a single articular facet on its head

FIG. 286.—The tenth, eleventh and twelfth ribs. Posterior aspect.

The **eleventh and twelfth ribs** (fig. 286) have each a single facet on the head, which is of rather large size; they have no necks or t and are pointed at their anterior ends. The eleventh has a slight a a shallow costal groove. The twelfth has neither; it is much shor the eleventh, and its vertebral end is directed slightly upwards. S the twelfth rib is shorter than the first.

Structure.—The ribs consist of highly vascular spongy substance en a thin layer of compact bone.

Ossification.—Each rib, with the exception of the first and the last two, is from four centres; a primary centre for the body, and three secondary cen for the head and one each for the articular and non-articular parts of the t The primary centre appears near the angle, towards the end of the secon of fœtal life, and is seen first in the sixth and seventh ribs. The secondar for the head and tubercle appear between the sixteenth and twentiet and unite with the body about the twenty-fifth year. The first rib h centres, viz.: a primary one for the body, a secondary centre for the h one for the tubercle. The eleventh and twelfth ribs, being destitute of t have each only two centres.

THE COSTAL CARTILAGES

The **costal cartilages** (fig. 278) are bars of hyaline cartilage which forwards from the anterior ends of the ribs and contribute very mate the elasticity of the walls of the thorax. The first seven pairs are co

* E. Fawcett states that 'in all probability there is usually no epiphysis on the no part of the tuberosity below the sixth or seventh rib' (*Journal of Anatomy and P* vol. xlv.).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the sternum; the eighth, ninth, and tenth are each articulated with the r border of the cartilage immediately above; the last two have pointed emities which end in the wall of the abdomen. The costal cartilages vary eir length, breadth, and direction. They increase in length from the first e seventh, then gradually decrease to the twelfth. They diminish in th from the first to the last, and so also do the intervals between them. are broad at their attachments to the ribs, and taper towards their medial emities, with the exception of the first and second which are of the same fth throughout, and the sixth, seventh, and eighth which are enlarged e their margins are in contact. The first cartilage descends a little, the d is horizontal, the third ascends slightly, while the others are angular, wing the course of the ribs for a short distance, and then ascending to the um or preceding cartilage.

ach costal cartilage has two surfaces, two borders, and two ends. The *ior surface* is convex, and looks forwards and upwards: that of the first attachment to the costoclavicular ligament and the Subclavius muscle; of the first six or seven at their medial ends, to the Pectoralis major. others are covered by, and give partial attachment to, some of the flat les of the abdomen. The *posterior surface* is concave, and directed back- s and downwards; that of the first gives attachment to the Sternothyreoi- those of the second to the sixth inclusive to the Transversus thoracis, e six inferior ones to the Transversus abdominis and the Diaphragm. *perior border* is concave, and the *inferior* convex; they afford attachment e Intercostales interni. The inferior borders of the sixth, seventh, eighth, ninth cartilages present heel-like projections at the points of greatest exity; a similar heel-like projection occurs on the lower border of the right cartilage in 72 per cent. and on the fifth left cartilage in 50 per cent. rcett). On these projections are oblong facets which articulate respectively facets on slight projections from the superior borders of the sixth, seventh, h, ninth, and tenth cartilages. The *lateral end* of each cartilage is con- ous with the osseous tissue of the rib to which it belongs. The *medial end* e first is continuous with the sternum: the medial ends of the six succeeding are rounded and articulate with shallow concavities on the lateral margins e sternum. The medial ends of the eighth, ninth, and tenth costal cartilages pointed, and each is connected with the cartilage immediately above. Those e eleventh and twelfth are pointed and free.

n old age the costal cartilages are prone to undergo superficial ossification.

THE THORAX

e skeleton of the **thorax**, or **chest** (fig. 287), is an osseocartilaginous which contains and protects the principal organs of respiration and lation. It is conical in shape, narrow above and broad below, flattened before backwards, and longer behind than in front. It is reniform on ontal section on account of the forward projection of the vertebral es.

Boundaries.—*Posteriorly* it is formed by the twelve thoracic vertebræ the posterior parts of the ribs. On either side of the vertebral column is ep groove in consequence of the lateral and backward direction which ribs take from their vertebral extremities to their angles. *Anteriorly* it is ed by the sternum and costal cartilages, and this surface is flattened or tly convex. *Laterally* it is convex, and is formed by the ribs. The ribs costal cartilages are separated from each other by the intercostal spaces, en in number, which are occupied by the Intercostal muscles and mem- nes.

e *upper opening* of the thorax is reniform in shape; its anteroposterior eter is about 5 cm., its transverse about 10 cm. It slopes downwards forwards, and is bounded by the first thoracic vertebra behind, the superior er of the manubrium sterni in front, and the first rib on either side. The *opening* is bounded by the twelfth thoracic vertebra behind, by the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

eleventh and twelfth ribs at the sides, and in front by the cartilages of the tenth, ninth, eighth, and seventh ribs, which ascend on either side to form an angle, the *subcostal angle*, into the apex of which the xiphoid process projects. The lower opening is wider transversely than from before backwards, and slopes obliquely downwards and backwards; it is closed by the Diaphragm, which forms the floor of the thorax.

FIG. 287.—The skeleton of the thorax. Anterior aspect.

The thorax of the female differs from that of the male as follows: 1. Its capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third dorsal vertebra, whereas in the male it is on a level with the lower part of the body of the second. 4. The upper ribs are more movable, and so allow a greater expansion of the upper part of the thorax.

Applied Anatomy.—Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages, which support it like springs. The fracture usually occurs in the upper half of the body. Dislocation of the body from the manubrium may take place, and is sometimes described as a fracture.

The ribs are frequently broken, though from their connexions and shape they are fitted to withstand great force, yielding under the injury and recovering themselves like springs. The middle ribs are the most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The injury generally occurs from indirect violence from forcible compression of the chest when the bone then gives way at its weakest part, i.e. just in front of the angle. But the ribs may also be broken by direct violence, in which case the bone is driven inwards at the point struck. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity; this is more likely to occur in fractures from direct violence.

Fracture of the costal cartilages, or separation of the cartilages from the ribs, is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

e place, though they are compared by injuries. In workmen the pressure of tools y displace the xiphoid process inwards.

The ribs are frequently the seat of tuberculous disease, with the formation of a chronic cess in the chest-wall. This may not immediately overlie the carious portion of rib, as pus is often directed a considerable distance along the costal groove before appearing ath the integument.

Resection of a portion of a rib is often required in order to give efficient drainage to an yema; this is referred to in the description of the respiratory organs.

Cervical ribs derived from the seventh cervical vetebra (page 169) are of not infrequent urrence, and are important clinically because they may give rise to nervous or vascular ptoms. The cervical rib may be a mere epiphysis articulating only with the trans- e process of the vertebra, but more commonly it consists of a defined head, neck and ercle, with or without a body. It extends lateralwards, or forwards and lateralwards, the posterior triangle of the neck, where it may terminate in a free end or may join first thoracic rib, the first costal cartilage, or the sternum.* It varies much in shape, direction, and mobility. If it reach far enough forwards, its relations are similar to e of the first thoracic rib; part of the brachial plexus and the subclavian artery and cross over it, and are apt to suffer compression in so doing. Pressure on the artery obstruct the circulation so much that arterial thrombosis results, causing gangrene he finger-tips. Pressure on the nerves is commoner, and affects the eighth cervical first thoracic nerves, causing paralysis of the muscles they supply, and neuralgic pains, hic changes and paræsthesia in the area of skin to which they are distributed: no lopupillary changes are to be found. If these symptoms be severe, removal of the rib much of it as causes pressure on the vessels and nerves is called for. The operation free from difficulty, and has been followed by paralysis of the muscles and by sub- n aneurysm, due to injuries inflicted in the course of the operation.

The *thorax* is frequently found to be altered in shape in certain diseases.

In *rickets*, the ends of the ribs, where they join the costal cartilages, become enlarged, ing rise to the so-called 'rickety rosary,' which in mild cases is only found on the internal face of the thorax. Lateral to these enlargements the softened ribs sink in, so as to sent a groove passing downwards and lateralwards on either side of the sternum. The s affected are the second to the eighth, the lower ones being prevented from falling in the presence of the liver, stomach, and spleen; and when the abdomen is distended, t often is in rickets, the lower ribs may be pushed outwards, causing a transverse groove arrison's sulcus) just above the costal arch. The sternum is forced forwards by the nding of the ribs, and the anteroposterior diameter of the thorax is increased; this formity, often asymmetrical, is known as *pigeon breast*. In many instances it is associated children with obstruction in the upper air-passages, due to enlarged tonsils or adenoid wths. In some rickety children or adults, and also in others who give no history or ther evidence of having had rickets, an opposite condition obtains. The lower part of sternum and often the xiphoid process as well are deeply depressed backwards, pro- ing an oval hollow in the lower sternal and upper epigastric regions; this is known 'funnel-breast.' The *phthisical chest* is often long and narrow, with great obliquity of ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in its diameters, and presents on section an almost circular outline. It has received the me of the 'barrel-shaped chest.' In severe cases of *lateral curvature of the vertebral column* thorax becomes much distorted. In consequence of the rotation of the bodies of the ebræ which takes place in this disease, the ribs opposite the convexity of the dorsal e become extremely convex behind, being thrown out and bulging, and at the same e flattened in front, so that the two ends of the same rib are almost parallel. Coinci- tly with this the ribs on the opposite side, on the concavity of the curve, are sunk and pressed behind, and bulging and convex in front.

More or less shrinkage of one side of the thorax is often seen as a consequence of hesive pleurisy, in which the pulmonary and parietal pleuræ adhere closely to one other and the lung becomes collapsed and fibrosed. If this process be at all complete, eat deformity of the chest results, the ribs on the affected side falling in, together with literation of the intercostal spaces; the contents of the mediastinal cavity are pulled er towards the affected side, and the other lung becomes emphysematous compensa- ily. The vertebral column becomes scoliotic, with the concavity of the curve towards affected side.

THE SKULL

The skull is supported on the top of the vertebral column, and is of an oid shape, wider behind than in front. It is composed of a series of flattened irregular bones which, with the exception of the mandible, are immovably nted together. It is divisible into: (1) the *cranium*, which consists of

* W. Thorburn, *The Med. Chronicle*, Manchester, 4th series, xiv. 1907.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

fifteen bones, and (2) the skeleton of the face, which consists of s follows :

Skull, 22 bones	*Cranium*, 15 bones	Occipital. Sphenoidal. Two Temporals. Two Parietals. Frontal. Ethmoidal. Two Inferior Nasal C Two Lacrimals. Two Nasals. Vomer.
	Face, 7 bones	Two Maxillæ. Two Palatines. Two Zygomatics. Mandible.

The hyoid bone, situated at the root of the tongue and attached to t of the skull by ligaments, is described in this section.

THE CRANIAL BONES (OSSA CRANII)

The Occipital Bone (Os Occipitale)

The **occipital bone** (figs. 288, 289), situated at the posterior and i part of the cranium, is trapezoid in shape and concave forwards. It is by a large oval aperture, the *foramen magnum*, through which the cranial communicates with the vertebral canal. The expanded plate abov behind this foramen is named the *squama* ; the thick, somewhat quadri piece in front of it is called the *basilar part* ; whilst on either side of it *lateral portion.*

The **squama** of the occipital bone, situated above and behind the fo magnum, is curved from above downwards and from side to side.

The *external surface* of the squama is convex and presents midway be the summit of the bone and the foramen magnum a prominence, the e *occipital protuberance.* Extending lateralwards from this on either sid two curved lines, one a little above the other. The upper line, often f marked, is named the *highest nuchal line* (linea nuchæ suprema), and to galea aponeurotica (epicranial aponeurosis) is attached. The lower l termed the *superior nuchal line.* The part of the external surface abo highest nuchal lines is named the *planum occipitale* ; it is smooth, and co with the Occipitalis muscle. The part below the highest nuchal line is te the *planum nuchale*, and is rough and irregular for the attachment of s muscles. From the external occipital protuberance a ridge, the *median line*, often faintly marked, descends to the foramen magnum, and a attachment to the ligamentum nuchæ ; running lateralwards from the m of this line on either side is the *inferior nuchal line.* Several muscles (fig are attached to the outer surface of the squama, thus : the superior n line gives origin to the Occipitalis and Trapezius, and insertion to the S cleidomastoideus and Splenius capitis ; into the surface between the su and inferior nuchal lines the Semispinalis capitis and the Obliquus c superior are inserted ; the inferior nuchal line and the area below it r the insertions of the Recti capitis posteriores major and minor. The po atlanto-occipital membrane is attached around the posterolateral part o foramen magnum, just outside the margin of the foramen.

The *internal surface* of the squama is deeply concave and divided into fossæ by a *cruciate eminence*, one limb of which is in the median sagittal the other transverse. The upper two fossæ are triangular, and lodg posterior parts of the occipital lobes of the cerebrum ; the lower tw quadrilateral and support the hemispheres of the cerebellum. At the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

intersection of the limbs of the cruciate eminence is the *internal occipital tuberance.* The upper division of the sagittal limb of the cruciate eminence s from this protuberance to the superior angle of the bone, and on one side t (generally the right) is a wide groove, the *sagittal sulcus,* which lodges hinder part of the superior sagittal sinus; to the margins of this sulcus the erior part of the falx cerebri is attached. The lower division of the sagittal b of the cruciate eminence is prominent, and is named the *internal occipital* ; it gives attachment to the falx cerebelli, and bifurcates near the foramen gnum; in the attached margin of this falx is the occipital sinus, which is metimes duplicated. At the lower part of the internal occipital crest, a ll depression is sometimes distinguishable; it is termed the *vermian fossa,*

FIG. 288.—The occipital bone. External aspect.

ce it is occupied by part of the vermis of the cerebellum. The right and left ts of the transverse limb of the cruciate eminence are each marked by a nsverse sulcus, which extends lateralwards from the internal occipital pro- berance; these sulci accommodate the transverse sinuses, and their margins e attachment to the tentorium cerebelli. The right transverse sulcus is ually larger than the left, and continuous with the sagittal sulcus; but the may be larger than the right, or the two may be almost equal in size. e angle of union of the superior sagittal and transverse sinuses is named the *fluence of the sinuses* or *torcular Herophili,** and its position is indicated a depression on one or other side of the protuberance.

The *superior angle* of the squama articulates with the occipital angles of parietal bones, and, in the fœtal skull, corresponds in position with the *pital fonticulus* (posterior fontanelle). The *lateral angles* are at the ends he transverse sulci; each is received into the interval between the mastoid gle of the parietal bone and the mastoid part of the temporal bone. The

lambdoid or superior borders extend from the superior to the lateral
they are serrated for articulation with the occipital borders of the parietal
and form by this union the lambdoid suture. The *mastoid or inferior*
extend from the lateral angles to the jugular processes; each articulat
the mastoid process of the corresponding temporal bone.

The **basilar part** of the occipital bone extends forwards and
from the foramen magnum, and presents *in front* a more or less quad
surface. In the young skull this surface is rough and uneven, and i

FIG. 289.—The occipital bone. Internal aspect.

to the body of the sphenoidal bone by a plate of cartilage. By the tw
fifth year this plate of cartilage has undergone ossification, and the occi
and sphenoidal bones are fused.

On the *inferior surface* of the basilar part, about 1 cm. in front of the for
magnum, is the *pharyngeal tubercle* which gives attachment to the fibrous
of the pharynx. On either side of the middle line the Longus capitis
Rectus capitis anterior are inserted, and immediately in front of the for
magnum the anterior atlanto-occipital membrane is attached.

The *superior surface* of the basilar part consists of a broad, shallow gr

The lateral parts of the occipital bone are situated at the sides of the men magnum; on their *inferior surfaces* are two oval processes, the *occipital yles*, for articulation with the superior facets of the atlas or first cervical bra. The condyles are oval or reniform in shape, with their long axes ng forwards and medialwards, so their anterior ends are closer her than their posterior, and oach on the basilar portion of the ; the posterior ends extend back e level of the middle of the foramen num. The articular surfaces of the yles are convex from before back- s and from side to side; they look wards and lateralwards, and are sionally constricted near their es. On the medial side of either is gh impression or tubercle for the igament. Above the anterior part her condyle is the *hypoglossal canal* rior condyloid foramen); this begins on the cranial surface of one a short distance above the ior part of the foramen magnum, is directed lateralwards and for- s. It may be partially or com- ly divided into two by a spicule one; it gives exit to the hypoglossal e, and entrance to a meningeal ch of the ascending pharyngeal artery. Behind either condyle is a depres- the *condyloid fossa*, which receives the posterior margin of the corresponding rior facet of the atlas when the head is bent backwards; the floor of this is sometimes perforated by the *condyloid canal*, through which an emissary passes from the transverse sinus. Extending lateralwards from the erior half of the condyle is the *jugular process*, a quadrilateral plate of e, indented in front by the *jugular notch* which, in the articulated skull, s the posterior part of the jugular foramen. The jugular notch is sometimes ded into two by a bony spicule, the *intrajugular process*, which projects ards and lateralwards. The under surface of the jugular process is rough, gives attachment to the Rectus capitis lateralis; from this surface an ence, the *paramastoid process*, sometimes projects downwards, and may f sufficient length to articulate with the transverse process of the atlas. rally the jugular process presents a rough quadrilateral or triangular which is joined to the jugular surface of the temporal bone by a plate rtilage; after the age of twenty-five this plate tends to ossify.

Fig. 290.—The occipital bone at birth. External aspect.

On the *superior surface* of the lateral part is an oval eminence, the *tuberculum lare*, which overlies the hypoglossal canal; behind this tubercle is a shallow ow for the glossopharyngeal, vagus, and accessory nerves. On the superior ace of the jugular process is a deep groove which curves medialwards and ards around an upwardly directed hook-shaped process, and ends at the lar notch. This groove lodges the terminal part of the transverse sinus, close to the medial margin of the groove, the condyloid canal opens.

The *foramen magnum* is a large oval aperture with its long diameter in median sagittal plane. The foramen is wider behind than in front, where it croached upon by the occipital condyles. It transmits the medulla oblon- and its membranes, the spinal portions of the accessory nerves, the vertebral ries, the anterior and posterior spinal arteries, the membrana tectoria, the alar ligaments.

Structure.—The occipital, like the other cranial bones, consists of two compact llæ, called the *outer and inner tables*, between which is the spongy substance *ploë*; the bone is thick at the ridges, protuberances and condyles, and at the rior portion of the basilar part; in the lower parts of the inferior fossæ it is thin, transparent, and destitute of diploë.

Ossification (fig. 290).—The part of the squama above the highest nuchal line

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is developed in membrane, and is ossified from two centres,* one app either side of the middle line about the second month of fœtal life; th the squama may remain separate throughout life, and is then known as *parietal bone.* The rest of the occipital bone is developed in cartilage. T part of the squama is ossified from two centres, which appear about the seve of fœtal life and soon unite to form a single piece. Union of the upper portions of the squama takes place in the third month of fœtal life. An centre appears in the posterior margin of the foramen magnum about the week (Kerckring); it unites with the rest of the squama before birth. the lateral parts ossifies from a single centre which appears during the eig of fœtal life. The basilar portion is ossified from one centre,* which appe the sixth week of fœtal life. About the fourth year the squama unites lateral portions, and about the sixth year the bone consists of a single piece. the eighteenth and twenty-fifth years the occipital and sphenoidal bones unit a single bone.

The Sphenoidal Bone (Os Sphenoidale)

The **sphenoidal body** (figs. 291 to 293) is situated at the base of th in front of the temporal bones and the basilar part of the occipit

Fig. 291.—The sphenoidal bone. Superior aspect.

It somewhat resembles a bat with wings extended, and consists of a portion or body, two great and two small wings extending lateralwards fro sides of the body, and two pterygoid processes which are directed down from the adjoining parts of the body and great wings.

The **body** of the sphenoidal bone, more or less cubical in shape, co two large cavities, the *sphenoidal air-sinuses*, separated from each other septum.

The *cerebral or superior surface* of the body (fig. 291) presents in fro *ethmoidal spine*, for articulation with the lamina cribrosa of the eth bone; behind this is a smooth surface, which is faintly grooved on eith of the middle line for the olfactory tracts of the brain. The superior s is bounded behind by a ridge, which forms the anterior border of a tran groove, the *sulcus chiasmatis* (optic groove); this sulcus ends on either s the *optic foramen.* Posterior to the sulcus is a more or less oval elev the *tuberculum sellæ*; and behind this is a deep depression, the *sella t* the deepest part of which lodges the hypophysis cerebri and is known a *fossa hypophyseos.* The anterior boundary of the sella turcica is com

* Mall, *American Journal of Anatomy*, vol. v. 1906.

erally by two small eminences, called the *middle clinoid processes*, whilst the terior boundary is formed by a square plate of bone, the *dorsum sellæ*; superior angles of this plate end in two tubercles, the *posterior clinoid cesses*, which vary considerably in form and size, and give attachment to lateral borders of the tentorium cerebelli. On either side of the dorsum e is a notch for the passage of the abducent nerve, and below this notch sharp process, the *petrosal process*, which articulates with the apex of the rous portion of the temporal bone. Behind the dorsum sellæ is a shallow pression, which slopes obliquely backwards, and is continuous with the llow groove on the superior surface of the basilar portion of the occipital ne; it supports the upper part of the pons.

The *lateral surfaces* of the body are united with the great wings and with medial pterygoid laminæ. Above the attachment of each wing is a broad ove, the *carotid sulcus*, curved somewhat like the italic letter *f*; it lodges

FIG. 292.—The sphenoidal bone. Posterior aspect.

internal carotid artery and the cavernous sinus. The carotid sulcus is pest at its posterior end where it is overhung by the petrosal process, and ted laterally by a sharp margin called the *lingula*; the latter is continued ckwards to overlie the posterior opening of the pterygoid canal.

The *posterior surface* of the body, quadrilateral in form (fig. 292), is joined, ing infancy and adolescence, to the basilar part of the occipital bone by late of cartilage which ossifies between the eighteenth and twenty-fifth years.

The *anterior surface* of the body (fig. 293) presents, in the middle line, a angular crest, the *sphenoidal crest*, which forms a small part of the septum the nose. The anterior border of this crest articulates with the lamina pendicularis of the ethmoidal bone; the lower border, with the vomer. either side of the crest is an opening leading into the corresponding *sphenoidal -sinus*.* The sphenoidal air-sinuses are two large, irregular cavities in body of the bone, separated from one another by a bony septum, which is mmonly bent to one or the other side. They vary considerably in form and e,† are seldom symmetrical, and are often partially subdivided by bony

* It may be stated here that the name 'sinus' is applied to two kinds of spaces associated the skull, viz.: (*a*) 'blood-sinuses' which produce grooves on the inner surfaces of some he bones, and (*b*) 'air-sinuses' which are cavities within some of the bones.

† Logan Turner (*The Accessory Sinuses of the Nose*, 1901) gives the following measurements an adult sphenoidal sinus of average size: height, 2 cm.; breadth, 1·8 cm.; anteroposterior th, 2·1 cm. Onodi (*The Accessory Sinuses of the Nose in Children*, 1911) states that in the -born infant their height is 4 mm. and their width 2 mm., while at the eighth year of life ir height is from 8 to 12 mm., and their width 11 mm.

The *cerebral or superior surface* of the great wing (fig. 291) forms part of floor of the middle fossa of the skull; it is deeply concave and presents ressions corresponding with the convolutions of the anterior part of the poral lobe of the brain. At its anteromedial part is a circular aperture, *foramen rotundum*, for the passage of the maxillary nerve. Behind and al to this foramen is the *foramen ovale*, for the transmission of the mandi- r nerve, the accessory meningeal artery, and sometimes the lesser superficial osal nerve.* Medial to the foramen ovale, a small aperture, the *foramen alii*, is often seen; when present it opens below at the lateral side of the hoid fossa, and transmits a small vein from the cavernous sinus. In the erior angle, near to but in front of the spina angularis, is a short canal, *foramen spinosum*, which transmits the middle meningeal artery and the rus spinosus.

The *lateral surface* of the great wing (fig. 293) is convex from above down- ds, and is divided by a transverse ridge, the *infratemporal crest*, into an er or temporal and a lower or infratemporal surface. The *temporal surface*, ave from before backwards, forms a portion of the temporal fossa, and s origin to a part of the Temporalis. The *infratemporal surface* is concave directed downwards; it forms a part of the infratemporal fossa, and, ther with the infratemporal crest, gives origin to the upper head of the tgoideus externus. It is pierced by the foramen ovale and foramen um, and at its posterior part is the spina angularis. Medial to the anterior mity of the infratemporal crest is a triangular process which serves to ase the attachment of the Pterygoideus externus. A ridge runs downwards medialwards from this triangular process to the front of the lateral pterygoid ina; it forms the anterior limit of the infratemporal surface, and, in the culated skull, the posterior boundary of the pterygomaxillary fissure.

The *orbital surface* of the great wing (fig. 293), quadrilateral in shape, is cted forwards and medialwards and forms the posterior part of the lateral l of the orbit. Its upper serrated edge articulates with the orbital plate the frontal bone; its lateral serrated margin with the zygomatic bone. inferior smooth border forms the posterolateral boundary of the inferior ital fissure. Its medial sharp margin constitutes the lower boundary of superior orbital fissure; projecting from near the centre of this margin is a ll tubercle which gives an attachment to part of the Rectus lateralis oculi. ow the medial end of the superior orbital fissure is a grooved surface, which ms the posterior wall of the pterygopalatine fossa, and is pierced by the men rotundum.

The margin of the great wing (fig. 291).—The portion of the margin of the at wing which extends from the body to the spina angularis is irregular. medial half forms the anterior boundary of the *foramen lacerum*, and presents posterior aperture of the pterygoid canal for the passage of the corresponding e and artery. Its lateral half articulates, by means of a synchondrosis, the petrous portion of the temporal bone, and between the two bones, he under surface of the skull, is a furrow, the *sulcus tubæ*, for the lodgment he cartilaginous part of the auditory tube. Extending forwards from the a angularis is the *squamosal margin*, a concave, serrated edge, bevelled he expense of the inner surface below, and of the outer surface above, for culation with the temporal squama. The tip of the great wing, or *parietal le*, is bevelled at the expense of the inner surface, and articulates with the enoidal angle of the parietal bone. Medial to this is a triangular rough a, for articulation with the frontal bone; the medial angle of this area is tinuous with the sharp edge which forms the lower boundary of the superior ital fissure, and the anterior angle with the serrated margin for articulation h the zygomatic bone.

The **small wings** (alæ parvæ) of the sphenoidal bone are two triangular tes, which project lateralwards from the upper and anterior parts of the body, end in sharp points (figs. 291, 292). The *cerebral surface* of each is smooth, supports a small part of the frontal lobe of the brain. The *inferior surface* ms the posterior part of the roof of the orbit, and the upper boundary of *superior orbital fissure*; it overhangs the anterior part of the middle fossa

* The lesser superficial petrosal nerve sometimes passes through a special canal (*canaliculus minatus* of Arnold) on the medial side of the foramen spinosum.

of the skull. The superior orbital fissure is triangular in shape, and l
the cranial cavity into that of the orbit; it is bounded medially by
of the sphenoidal bone; above, by the small wing; below, by the
margin of the orbital surface of the great wing; and is completed
between the great and small wings, by the frontal bone. It transmits
orbital cavity the oculomotor, trochlear, and abducent nerves, the three
of the ophthalmic division of the trigeminal nerve, and some filaments
the cavernous plexus of the sympathetic; and from the orbital ca
recurrent meningeal branch of the lacrimal artery, and the ophthalmic
The *frontal or anterior border* of the small wing is serrated for articulation
the posterior edge of the orbital plate of the frontal bone. The *posterior*
is smooth and projects into the lateral cerebral fissure; the medial end
border forms the *anterior clinoid process* which gives attachment to the
end of the free border of the tentorium cerebelli. The anterior and
clinoid processes are sometimes united by a spicule of bone, and w
occurs the end of the groove for the internal carotid artery is converted
foramen (*caroticoclinoid foramen*). The small wing is connected to th
by two roots, the upper thin and flat, the lower thick and triangular;
these is the *optic foramen*, for the transmission of the optic nerve and oph
artery to the orbital cavity.

The **pterygoid processes** of the sphenoidal bone (figs. 292, 293), on
either side, descend perpendicularly from the regions where the body and
wings unite. Each process consists of a medial and a lateral lamina, the
parts of which are fused anteriorly; a shallow groove, the *pterygo*
sulcus, descends on the front of the line of fusion, and forms, in the arti
skull, the posterior wall of the pterygopalatine canal. The laminæ are se
below by an angular cleft, the *pterygoid fissure*, the rough margins o
articulate with the pyramidal process of the palatine bone. The two
diverge behind, and between them is the wedge-shaped *pterygoid fossa*
contains the Pterygoideus internus and Tensor veli palatini. Abo
fossa is a small, oval, shallow depression, the *scaphoid fossa*, which
origin to part of the Tensor veli palatini. The anterior surface
pterygoid process is broad and triangular near its root, where it
the posterior wall of the pterygopalatine fossa; on it is the anterior orifice
pterygoid canal.

The *lateral lamina* of the pterygoid process is broad, thin, and e
its *lateral surface* forms part of the medial wall of the infratemporal fossa
gives origin to the lower head of the Pterygoideus externus; its *medial*
forms the lateral wall of the pterygoid fossa, and gives origin to the great
of the Pterygoideus internus. The lower part of its *anterior border* arti
with the palatine bone; its *posterior border* is free.

The *medial lamina* of the pterygoid process is narrower and longer th
lateral; its lower extremity curves lateralwards into a hook-like p
the *pterygoid hamulus*, around which the tendon of the Tensor veli p
glides. The *lateral surface* of this lamina forms the medial wall of the pte
fossa, and the Tensor veli palatini lies against it; the *medial surface* cons
the lateral boundary of the choana or posterior aperture of the corresp
nasal cavity. Superiorly the medial lamina is prolonged on to the
surface of the body as a thin plate, named the *vaginal process*, which arti
anteriorly with the sphenoidal process of the palatine bone and mediall
the ala of the vomer. On the under surface of the vaginal process is a
which is converted into a canal by the sphenoidal process of the palatine
this canal transmits the pharyngeal branch of the internal maxillary
and the pharyngeal nerve from the sphenopalatine ganglion. The po
margin of the medial lamina gives attachment in its entire length
pharyngobasilar fascia (pharyngeal aponeurosis), and from the lower one
of this margin the Constrictor pharyngis superior takes origin. At the
end of this margin is a small pyramidal process named the *pterygoid t*
immediately above which is the posterior opening of the pterygoid
Projecting backwards from near the middle of the margin is an angular p
the *processus tubarius*, which supports the pharyngeal end of the au
tube. The anterior margin of the lamina articulates with the posterior
of the vertical part of the palatine bone.

The sphenoidal conchæ (fig. 293) are two thin, curved plates, situated at anterior and lower parts of the body of the sphenoidal bone; the upper, cave surface of each forms the anterior wall and a part of the floor of corresponding sphenoidal air-sinus. The sphenoidal conchæ are usually e or less destroyed in the process of disarticulating the skull, but when *in situ*, each consists of an anterior, vertical, quadrilateral part and a erior, horizontal, triangular part. The anterior, vertical portion consists (*a*) an upper and lateral, depressed area which completes the posterior noidal air-sinuses and articulates below with the orbital process of the atine bone: and (*b*) a lower and medial area, smooth and triangular, which ms part of the roof of the nasal cavity, and is perforated near its superior le by a round opening through which the sphenoidal air-sinus com- nicates with the spheno-ethmoidal recess of the nasal cavity. The anterior, tical portions of the two bones meet in the middle line, and are protruded rwards as the sphenoidal crest. The horizontal triangular portion of concha forms a part the roof of the nasal ity, and completes the enopalatine foramen; its tial margin articulates the rostrum of the hoidal bone, and with ala of the vomer; its x, directed backwards, medial to and above the inal process of the medial rygoid lamina, and arti- ates with the posterior t of the ala of the vomer.

FIG. 294.—The sphenoidal bone at birth. Posterior aspect.

small piece of the sphenoidal concha sometimes appears in the medial wall the orbit, between the lamina papyracea of the ethmoidal bone in front, the bital plate of the palatine bone below, and the frontal bone above.

Ossification.—Until the seventh or eighth month of fœtal life the body of the henoidal bone consists of two parts—viz. one in front of the tuberculum sellæ, e *presphenoidal part*, with which the small wings are continuous; the other mprising the sella turcica and dorsum sellæ, the *postsphenoidal part*, with which e great wings, and pterygoid processes are associated. A considerable part of e bone is ossified in cartilage. There are six centres for the presphenoidal and ht for the postsphenoidal part.

Presphenoidal part. About the ninth week of fœtal life a centre of ossification pears for each of the small wings, just lateral to the optic foramen; shortly rwards two centres appear in the presphenoidal part of the body. The sphenoidal chæ are each developed from a centre which makes its appearance about the h month*; at birth they consist of small triangular laminæ; about the third r they become hollowed out and cone-shaped; about the fourth year they e with the labyrinths of the ethmoidal bone, and between the ninth and twelfth ars with the sphenoidal bone.

Postsphenoidal part.—The first centres of ossification are those for the great ngs. One appears below the foramen rotundum in the cartilage which forms e base of each wing about the eighth week. The following portions of the great ng are ossified in membrane, viz.: the parts surrounding the foramen ovale d foramen spinosum, the orbital plate, and the part found in the temporal fossa.† bout the fourth month, two centres appear in the postsphenoidal part of the dy, one on either side of the sella turcica, and fuse about the middle of fœtal e. Each medial pterygoid lamina (with the exception of its hamulus) is ossified membrane, and its centre probably appears about the ninth or tenth week; e hamulus is chondrified during the third month, and almost at once begins ossify.‡ The medial and lateral pterygoid laminæ join about the sixth month. bout the fourth month a centre appears for each lingula and speedily joins the st of the bone.

* According to Cleland, each sphenoidal concha is ossified from four centres.

† E. Fawcett, *Journal of Anatomy and Physiology*, vol. xliv. 1910.

The presphenoidal and the postsphenoidal parts of the body fuse at eighth month of fœtal life, and at birth the bone is in three pieces (fig. 294): consisting of the body and small wings, and two lateral, each comprising a and pterygoid process. In the first year after birth the great wings and and the small wings extend medialwards above the anterior part of the meet to form an elevated smooth surface, termed the *jugum sphenoidale*. twenty-fifth year the sphenoidal and occipital bones are completely fused. anterior part of the fossa hypophyseos there are occasionally seen the the *canalis craniopharyngeus*, through which, in early fœtal life, the diverticulum of the buccal ectoderm is transmitted (p. 135).

Traces of the sphenoidal air-sinuses are seen as early as the third month life, but they do not attain their full size until after puberty.

Certain parts of the sphenoidal bone are connected by ligaments which ossify. The more important of these ligaments are: the *pterygospinous*, between the spina angularis and the upper part of the lateral pterygoid lamina *colli*); the *interclinoid*, joining the anterior to the posterior clinoid process; *caroticoclinoid*, connecting the anterior to the middle clinoid process.

Applied Anatomy.—Premature ossification or synostosis of the suture between and postsphenoidal parts (which normally begins to join at the eighth month) sphenobasilar suture produces a characteristic physiognomy. This is best seen in and consists in an abnormal depression of the bridge of the nose; it is a featu observed in dwarfs.

Tumours and cysts of the hypophysis are removed by gaining access to the fo physeos, either from below through the nose and the spenoidal air-sinuses, or fro by raising the brain from the anterior fossa of the cranial cavity.

The Temporal Bones (Ossa Temporalia)

The **temporal bones** are situated at the sides and base of the skull. consists of five parts, viz. the *squama*, the *mastoid*, *petrous*, and *tympanic* and the *styloid process*.

The **squama** of the temporal bone forms the anterior and upper parts bone, and is scale-like, thin and translucent. Its *temporal or external* (fig. 295) is smooth and slightly convex; it forms part of the tempora and gives origin to the Temporalis muscle; on its hinder part, abo opening of the external acoustic meatus, is a vertical groove for the temporal artery. A curved line, the *temporal line* or *supramastoid crest*, backwards and upwards, across its posterior part; it serves for the attac of the temporal fascia, and limits the origin of the Temporalis muscle. boundary between the squama and the mastoid portion of the bone lies 1·5 cm. below the temporal line, and is frequently indicated by traces original squamosomastoid suture; the external surface of this lower p the squama is convex, and from its anterior part the Auricularis posterior origin. Between the anterior end of the temporal line and the posterosu sector of the opening of the external acoustic meatus is an angular depre the *suprameatal triangle* of Macewen; through this triangle an instru may be pushed into the tympanic antrum.

Projecting from the lower part of the squama is a long, arched proce *zygomatic process*. The posterior part of this process is triangular in and springs from a broad base; it is directed lateralwards, and its faces are superior and inferior. The process is then twisted inwards runs forwards, and the surfaces of this anterior portion are therefore and lateral. The superior surface of the posterior part is concave continuous with the temporal surface of the squama; the inferior surf bounded by two roots, a *posterior* and an *anterior*, which converge as approach the anterior part of the process. At the meeting point of the roots is a small tubercle for the attachment of the temporomandibular ment. The posterior root is prolonged forwards from the surface of the sq immediately above the opening of the external acoustic meatus; its border is continuous behind with the temporal line. The anterior root almost horizontally from the side of the squama; its inferior surface, from before backwards, is smooth for articulation with the articular disc

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ndibular joint, and the whole root presents the form of a short semi-
indrical bar, termed the *articular tubercle* (eminentia articularis). The
icular tubercle forms the anterior boundary of the mandibular fossa.
The anterior part of the zygomatic process is thin and flat. The superior
der, long and thin, gives attachment to the temporal fascia; the inferior,
t and arched, gives origin to some fibres of the Masseter. The lateral
ace is convex and subcutaneous; the medial is concave, and gives origin
part of the Masseter. The anterior end is deeply serrated and cut obliquely
the expense of the lower border; it articulates with the temporal process of
zygomatic bone. In front of the articular tubercle is a small triangular
which forms a part of the infratemporal fossa, and is separated from the

FIG. 295.—The left temporal bone. External aspect.

er surface of the squama by a ridge; this ridge is continuous behind with the
erior root of the zygomatic process, and in front, in the articulated skull,
h the infratemporal crest on the great wing of the sphenoidal bone. The
ndibular fossa (glenoid fossa) is bounded in front by the articular tubercle;
consists of an anterior, articular portion, formed by the squama, and a
terior non-articular portion, formed by the tympanic part of the
mporal bone. The articular portion, smooth, oval and deeply concave,
culates with the articular disc of the mandibular joint; the non-articular
tion sometimes lodges a small part of the parotid gland. A small, some-
at conical, eminence, the *postglenoid tubercle*, separates the lateral part
the articular portion from the anterior margin of the tympanic part of the
e, and is the representative of a prominent tubercle which, in some mammals,
ends behind the condyle of the mandible, and prevents its backward
placement; the postglenoid tubercle is sometimes described as the third
of the zygomatic process. The medial part of the articular portion of
mandibular fossa is separated from the tympanic part of the bone by the
er edge of a plate which projects downwards from the tegmen tympani

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the petrous part of the bone; between this plate and the tympani the *petrotympanic fissure* (Glaserian fissure). This fissure leads into the ear or tympanic cavity; it lodges the anterior process of the malle transmits the anterior tympanic branch of the internal maxillary arter medial end of the fissure is known as the *canal of Huguier*; it trans chorda tympani nerve.

The *cerebral or internal surface* of the squama (fig. 296) is concave; it depressions corresponding to the convolutions of the temporal lobe of th and grooves for the branches of the middle meningeal vessels; its lower is united to the anterior surface of the petrous portion by the *petrosq* suture, traces of which are frequently seen in the adult bone.

FIG. 296.—The left temporal bone. Internal aspect.

The *parietal or superior border* is thin, bevelled at the expense of the in surface, and overlaps the squamous border of the parietal bone, forming it the squamosal suture. Posteriorly, the superior border forms an the *parietal notch*, with the mastoid portion of the bone. The *sphenoi antero-inferior border*, thin above and thick below, articulates with the wing of the sphenoidal bone; its upper part is bevelled at the expense inner, its lower at the expense of the outer, surface.

The **mastoid portion** of the temporal bone forms the posterior p the bone. Its *outer surface* (fig. 295) is rough, and gives attachment t Occipitalis, and Auricularis posterior. It is frequently perforated near t terior border by the *mastoid foramen* which transmits a vein from the tran sinus, and a small branch of the occipital artery to the dura mater; the p and size of this foramen are very variable; it may be situated in the oc bone, or in the suture between the temporal and the occipital bones. mastoid portion is continued below into a conical projection, the *mastoid p* the size and form of which vary somewhat; it is larger in the male th the female. This process serves for the attachment of the Sterno

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

stoideus, Splenius capitis, and Longissimus capitis; on the medial side is a p groove, the *mastoid notch* (digastric fossa), for the attachment of the terior belly of the Digastricus; medial to this notch is a shallow furrow, *occipital groove*, which lodges the occipital artery.

On the *inner surface* of the mastoid portion (fig. 296) there is a deep, ved groove, the *sulcus sigmoideus*, which lodges part of the transverse sinus; this sulcus is the opening of the mastoid foramen. The sulcus sigmoideus is arated from the innermost of the mastoid air-sinuses by a thin lamina of e which may be partly deficient.

The *superior border* of the mastoid portion is thick and serrated for arti- ation with the mastoid angle of the parietal bone. The *posterior border*, o serrated, articulates with the inferior border of the occipital bone between

FIG. 297.—A coronal section through the right temporal bone. Anterior aspect.

lateral angle and jugular process. Anteriorly the mastoid portion is fused h the descending process of the squama above; below it enters into the mation of the posterior wall of the tympanic cavity.

A section of the mastoid process (fig. 297) exhibits a number of spaces, *mastoid air-sinuses*, which vary greatly in size and number. At the upper d front part of the process they are large and irregular, but towards the er part they diminish in size, while those at the apex of the process are quently quite small; occasionally they are entirely absent, and the mastoid then solid throughout. In addition to the mastoid air-sinuses a large egular air-sinus, the *tympanic antrum* (mastoid antrum) is situated in e upper and front part of the process; it is lined with a prolongation of e mucous membrane of the tympanic cavity. It is bounded above by a thin te of bone, the *tegmen tympani*, which separates it from the middle fossa the base of the skull; laterally by the part of the squama which lies below e supramastoid crest; on its medial wall is the lateral semicircular canal the internal ear. Below and behind, the tympanic antrum communicates h the mastoid air-sinuses; in front it opens into that portion of the mpanic cavity which is known as the *attic* or *epitympanic recess*. The mpanic antrum is a cavity of some considerable size at the time of birth;

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the mastoid air sinuses originate as diverticula from the antrum, a to appear at or before birth; by the fifth year they are of consider but their development is not completed until puberty.

The **petrous portion** or **pyramid** of the temporal bone is wedged the sphenoidal and occipital bones at the base of the skull (figs. 3 It is directed medialwards, forwards, and a little upwards, and has an apex, three surfaces, and three angles (margins). The essential the organs of hearing and equilibrium are placed within it.

The *base* is fused with the squama and the mastoid portion.

The *apex*, rough and uneven, is received into the angular interval the posterior border of the great wing of the sphenoidal bone and the part of the occipital bone; it is pierced by the anterior or internal orifi carotid canal, and forms the posterolateral boundary of the foramen lac

The *anterior surface* forms the posterior part of the middle fossa skull, and is continuous with the inner surface of the squama, to whi united by the *petrosquamosal suture*, remains of which are distinct a late period of life. It is marked by depressions for the convolutions

FIG. 298.—A diagrammatic view of the lateral end of the right internal acou meatus. (Testut.)

brain, and presents six points for examination: (1) near the centre *eminentia arcuata*, which indicates the situation of the superior semic canal; (2) in front of and lateral to this eminence is a depressed area forms the roof of the tympanic cavity and consists of a thin plate of known as the *tegmen tympani*; a thin scale of this descends betwee squama and the tympanic plate, and forms the anterior boundary of the tympanic fissure, and the greater part of the lateral wall of the sem for the Tensor tympani muscle; (3) a shallow groove, sometimes d leads backwards and lateralwards to an oblique opening, the *hiatus of the canal*, for the passage of the greater superficial petrosal nerve and the p branch of the middle meningeal artery; (4) lateral to the hiatus th occasionally a smaller opening for the passage of the lesser superficial p nerve; (5) near the apex of the bone is the end of the carotid canal, the an wall of which is deficient; (6) above this canal is the shallow *trigeminal imp* for the reception of the semilunar ganglion of the trigeminal nerve.

The *posterior surface* (fig. 296) forms the anterior part of the posterior of the skull, and is continuous with the inner surface of the mastoid p Near the centre of this surface is an orifice of varying size, the *porus ac internus* leading into the *internal acoustic meatus*, a canal, about 1 cm. in le which runs lateralwards. It transmits the facial and acoustic nerves an internal auditory branch of the basilar artery. The lateral end of the int acoustic meatus is separated from the internal ear by a vertical plate, is divided by a horizontal crest, the *crista transversa*, into two unequal pe

298). Below the posterior part of the crista transversa, and situated e *area vestibularis inferior* are several small openings for the transmission e nerves to the saccule; below and behind this area is the *foramen singulare*, h gives passage to the nerve to the posterior semicircular duct. Below nterior part of the crista transversa is the *tractus spiralis foraminosus*, sting of a number of small spirally arranged openings, which encircle *analis centralis cochleæ*; these openings together with the canalis centralis leæ transmit the nerves to the cochlea. The portion above the crista sversa displays behind, the *area vestibularis superior*, pierced by a series nall openings for the passage of the nerves to the utricle and the superior lateral semicircular ducts, and, in front, the *area facialis*, with one large ing which is the commencement of the *canalis facialis* (aquæductus Fallopii)

FIG. 299.—The left temporal bone. Inferior aspect.

transmits the facial nerve. Behind the porus acusticus internus is a small almost hidden by a thin plate of bone, leading to a canal, the *aquæductus buli*, which contains the ductus endolymphaticus together with a small artery vein. Above and between these two openings is an irregular depression h lodges a process of the dura mater and transmits a small vein; in the infant depression is represented by a large fossa, the *fossa subarcuata*, which extends wards as a short, blind tunnel under the superior semicircular canal.

The *inferior surface* (fig. 299), rough and irregular, forms part of the rnal surface of the base of the skull. It presents the following parts for mination: (1) near the apex is a quadrilateral rough surface, which serves ly for the attachment of the Levator veli palatini and the cartilaginous por- of the auditory tube, and partly for connexion with the basilar part of the pital bone through the intervention of some dense fibrous tissue; (2) behind is a large, nearly circular aperture, the inferior opening of the *carotid canal*; canal runs at first vertically, and then, making a bend, is directed hori- ally forwards and medialwards; it transmits into the cranium the internal tid artery, and the carotid plexus of nerves; (3) behind this opening is a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

deep depression, the *jugular fossa*, of variable depth and size in differe
it lodges the bulb of the internal jugular vein ; (4) in front of the me
of the jugular fossa and directly below the porus acusticus internus is a t
depression ; at the apex of this depression is a small opening, the a
cochleæ, which lodges a tubular prolongation of the dura mater, and t
a vein from the cochlea to join the internal jugular vein ; (5) in the b
dividing the carotid canal from the jugular fossa is the small *inferior*
canaliculus for the passage of the tympanic branch of the glossoph
nerve (nerve of Jacobson) ; (6) in the lateral part of the jugular fo
mastoid canaliculus for the entrance of the auricular branch of the vag
(nerve of Arnold) ; (7) behind the jugular fossa is the *jugular surface*,
quadrilateral area covered with cartilage in the recent state, and art
with the jugular process of the occipital bone ; (8) extending late
from the carotid canal is the sharp lower border of the tympanic pa
bone ; the lateral part of this border splits to ensheath the root of the
process and is therefore named the *vagina processus styloidei* (vaginal p
(9) emerging from its sheath is the *styloid process*, which is about 2·5
length, and is directed downwards and forwards ; (10) between the
and mastoid processes is the *stylomastoid foramen* ; this foramen is the en
facial canal, and transmits the facial nerve and stylomastoid artery.

The *superior angle* (superior margin), the longest, is grooved for the s
petrosal sinus, and gives attachment to the tentorium cerebelli ; at its
extremity is a shallow notch, in which the trigeminal nerve lies. The p
angle (posterior margin) is intermediate in length between the super
the anterior. Its medial part is marked by a sulcus, which forms,
corresponding sulcus on the occipital bone, the channel for the inferior
sinus. Behind this is the *jugular fossa* which, with the jugular notch
occipital bone, forms the jugular foramen ; an eminence occasionally
from the centre of the fossa, and divides the foramen into two. The
angle (anterior margin) is divided into two parts—a lateral, joined to the
at the *petrosquamosal* suture ; a medial, free, for articulation with th
wing of the sphenoidal bone.

At the angle of junction of the petrous part and the squama are tw
placed one above the other, and separated by a thin plate of bone, the
canalis musculotubarii (processus cochleariformis). Both canals lead i
tympanic cavity ; the upper (semicanalis m. tensoris tympani) tr
the Tensor tympani, the lower (semicanalis tubæ auditivæ) forms th
part of the auditory tube.

The **tympanic part** of the temporal bone (fig. 299) is a curved pla
below the squama and in front of the mastoid process. Internally, it
with the petrous portion, and appears in the angle between it and the s
where it lies below and lateral to the orifice of the auditory tube. B
fuses with the squama and the mastoid process, and forms the anterior bo
of the tympanomastoid fissure. Its *posterior surface* is concave, and
the anterior wall, the floor, and a part of the posterior wall of the bony e
acoustic meatus ; at the medial end of this surface is a narrow furr
tympanic sulcus, for the attachment of the circumference of the ty
membrane. Its *anterior surface*, quadrilateral and slightly concave, con
the posterior wall of the mandibular fossa, and is sometimes in conta
a part of the parotid gland. Its *lateral border*, free and rough, forms
part of the margin of the *porus acusticus externus*, and gives attachment
cartilaginous part of the external acoustic meatus, The lateral part
upper border is fused with the back of the postglenoid process ; its med
forms the posterior boundary of the petrotympanic fissure. The *lower b*
sharp ; its lateral part splits to enclose the root of the styloid process
therefore named the vagina processus styloidei (vaginal process). The
portion of the tympanic part of the temporal bone is thin, and in
siderable percentage of skulls is perforated by the *foramen of Huschke*.

The *external acoustic meatus*, about 16 mm. long, is directed inwar
slightly forwards and downwards, and the floor of the meatus is convex up
In sagittal section the meatus is oval or elliptical in shape with the lo
directed downwards and slightly backwards. Its anterior wall and flo
the lower part of its posterior wall are formed by the tympanic part

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

e; the roof and the upper part of the posterior wall by the squama. Its r end is closed, in the recent state, by the tympanic membrane; its r end (*porus acusticus externus*) is bounded above by the posterior root he zygomatic process, below which a small spine, the *suprameatal spine*, metimes seen at the upper and posterior part of the orifice.

The styloid process of the temporal bone, slender, pointed, and averaging rt 2·5 cm. in length, projects downwards and forwards, from the under ace of the temporal bone. Its proximal part (tympanohyal) is surrounded by heath (vagina processus styloidei), while its distal part (stylohyal) gives chment to the stylohyoid and stylomandibular ligaments, and to the oglossus, Stylohyoideus and Stylopharyngeus muscles.

Structure.—The structure of the squama is like that of the other cranial bones: mastoid portion is spongy, and the petrous portion dense and hard.

Ossification.—The temporal bone is ossified from eight centres (exclusive of e for the internal ear and the tympanic ossicles)—viz. one each for the squama the tympanic part, four for the petrous and mastoid parts, and two for the

FIG. 300.—The three principal parts of the right temporal bone at birth.

xternal aspect of petromastoid part. 2. Internal aspect of tympanic ring. 3. Internal aspect of squama.

oid process. Just before the close of fœtal life the bone consists of three principal ts, viz.: the squama, the petromastoid part, and the tympanic ring (fig. 300). *squama* is ossified in membrane from a single centre which appears near the of the zygomatic process about the seventh or eighth week of fœtal life. The *mastoid* part is developed from four centres, which make their appearance he cartilaginous ear-capsule (p. 107) about the fifth or sixth month of fœtal life. e (pro-otic) appears in the neighbourhood of the eminentia arcuata, spreads in t of and above the internal acoustic meatus and extends to the apex of the bone; overs part of the cochlea, vestibule, superior semicircular canal, and medial wall he tympanic cavity. A second (opisthotic) appears at the promontory on the dial wall of the tympanic cavity and surrounds the fenestra cochleæ; it forms floor of the tympanic cavity and vestibule, surrounds the carotid canal, invests lateral and lower parts of the cochlea, and spreads medially below the internal ustic meatus. A third (pterotic) roofs in the tympanic cavity and antrum; while fourth (epiotic) appears near the posterior semicircular canal and extends to m the mastoid process (Vrolik). The *tympanic ring* is an incomplete circle concavity of which is grooved by the tympanic sulcus, for the attachment of circumference of the tympanic membrane.* The tympanic ring expands to m the tympanic part of the bone, and is ossified in membrane from a single re which appears about the third month. The *styloid process* is developed m the cranial end of the cartilage of the second branchial or hyoid arch (p. 77)

* Two crests, the *superior and inferior tympanic crests*, run obliquely downwards and forwards ss the anterior part of the inner surface of the tympanic ring. Between them is an obliquely ected furrow, the *sulcus malleolaris*, which lodges the anterior process of the malleus, the erior tympanic artery and the chorda tympani nerve.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

by two centres: one for the proximal part of the process, the tympanohyal before birth; the other, for the distal part of the process, the stylohyal, appear until aft The tympanic rin with the squama before birth; the mastoid part a squama join dur first year, and th panohyal portion styloid process al same time (figs. 3 The stylohyal do unite with the res bone until after and in some skull at all.

Fig. 301.—The temporal bone at birth. External aspect.

The chief sub changes in the te bone apart from inc size are: (1) The tym ring grows lateralward backwards to form th panic part of the bone. This extension does not, however, take place at a rate all round the circumference of the ring, but occurs most rapidly on its a and posterior portions, and these outgrowths meet and blend, and thus, for there exists in the floor of the meatus a foramen, the *foramen of Huschk* foramen is usually closed about the fifth year, but may persist througho (2) The mandibular fossa is at first extremely shallow, and looks more later than downwards; it becomes deeper and is ultimately directed downward change in direction is accounted for as follows. The part of the squama which forms the fossa lies at first below the level of the zygomatic process and is nearly vertical, but in consequence of the subsequent increase in the width of the base of the skull this part of the squama comes to be directed horizontally inwards, and its surfaces therefore upwards and downwards; the attached portion of the zygomatic process also becomes everted and projects like a shelf at right angles to the squama. (3) The mastoid portion is at first flat, and the stylomastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the mastoid air-sinuses the lateral part of the mastoid portion grows downwards and forwards to form the mastoid process, and the styloid process and stylomastoid foramen come to lie on the under surface of the bone. The descent of the stylomastoid foramen is nece accompanied by a corresponding increase in the length of the canal for the nerve. (4) The downward and forward growth of the mastoid process also forward the tympanic part of the bone, so that the portion of the latter which the original floor of the external acoustic meatus and contained the fora Huschke ultimately constitutes the anterior wall of the meatus. (5) The subarcuata on the posterior surface of the petrous portion is gradually fill almost obliterated.

Fig. 302.—The temporal bone Internal aspect.

Applied Anatomy.—The external acoustic meatus is relatively as long in the in the adult, but in the child the canal is cartilaginous, whereas in the adult th

thirds of it are osseous. When it is necessary to open the tympanum for suppuration, approached through the tympanic antrum. In the child only a thin scale of bone es to be removed from the suprameatal triangle to open into the tympanic antrum.

The Parietal Bones (Ossa Parietalia)

The **parietal bones** form, by their union, the sides and the roof of the um. Each bone is irregularly quadrilateral in shape, and has two surfaces, borders, and four angles.

Fig. 303.—The left parietal bone. External aspect.

The *parietal* or *external surface* (fig. 303) is convex, smooth, and marked the centre by an eminence, the *parietal tuberosity or eminence.* Crossing middle of the bone in an arched direction are two curved lines, the *superior inferior temporal lines*; the former gives attachment to the temporal a, and the latter indicates the upper limit of the origin of the Temporalis. part of the bone above these lines is covered, in the recent condition, with galea aponeurotica; that below the lines forms a part of the temporal . At the posterior part and close to the upper or sagittal border is the *etal foramen*, which transmits a vein from the superior sagittal sinus, and times a small branch of the occipital artery; the foramen is not constantly nt, and its size varies considerably.

The *cerebral or internal surface* (fig. 304) is concave; it presents depressions sponding to the cerebral convolutions, and numerous furrows for the fications of the middle meningeal vessels *; these furrows run upwards

asterion. On the internal surface of this angle is a broad, shallow groove h lodges a small part of the transverse sinus.

t birth there are unossified or membranous intervals in the skull at the s of the parietal bones; they are named fonticuli (fontanelles) and are ribed on pp. 267, 268.

ssification.—The parietal bone is ossified in membrane from two centres, n appear one above the other at the parietal tuberosity about the seventh of fœtal life. These centres unite early, and ossification gradually extends radial manner towards the margins of the bone; the angles are consequently parts last formed, and it is here that the fonticuli are found. At birth the oral lines are situated low down; they only reach their permanent position the eruption of the molar teeth. Occasionally the parietal bone is divided into parts, upper and lower, by an anteroposterior suture.

The Frontal Bone (Os Frontale)

he **frontal bone** resembles a cockle-shell in form, and consists of two ons—a vertical part, the *squama*, corresponding with the region of the ead; and a horizontal or *orbital part*, which enters into the formation roofs of the orbital and nasal cavities.

e **squama** of the frontal bone has two surfaces, an external and an nal.

he *external surface* of the squama (fig. 305) is convex and divided into a frontal and two small temporal surfaces by lines which arch backwards s the lateral parts of the bone.

he *frontal surface* usually exhibits, in the lower part of the middle line, remains of the *frontal or metopic suture*; in infancy this suture divides bone into two, a condition which persists in about 9 per cent. of skulls. ither side of the middle line, about 3 cm. above the supra-orbital margin, rounded elevation, the *frontal tuberosity or eminence.* These tuberosities in size in different individuals, are occasionally unsymmetrical, and are cially prominent in young skulls. Below the frontal tuberosities, and rated from them by a shallow groove, are two curved elevations, the *rciliary arches*, the medial parts of which are prominent, and joined to one her by a smooth elevation named the *glabella.* These arches are larger e male than in the female, and their degree of prominence depends to some nt on the size of the frontal air-sinuses; prominent superciliary arches however, occasionally associated with small air-sinuses. Beneath the rciliary arches are the curved *supra-orbital margins*, which form the upper daries of the bases of the orbits, and separate the squama from the orbital on of the bone. The lateral two-thirds of each supra-orbital margin is p; the medial one-third is rounded. At the junction of these two parts is *upra-orbital notch or foramen* which transmits the supra-orbital vessels and e. Medial to this notch, and present in about 50 per cent. of skulls, is small *frontal notch or foramen.* The supra-orbital margin ends laterally e *zygomatic process*, which is strong and prominent, and articulates with zygomatic bone. Curving upwards and backwards from this process is a which soon divides into the *superior and inferior temporal lines.*

he portion of the squama which projects downwards between the supra- al margins is named the *nasal part.* It presents an uneven interval, the *l notch*, which articulates on either side of the middle line with the nasal , and lateral to this with the frontal process of the maxilla and with the mal bone. From the centre of the notch the *nasal process* projects down- ds and forwards beneath the nasal bones and frontal processes of the maxillæ, supports the bridge of the nose. The nasal process ends below in a sharp *al spine*, and on either side of this is a small grooved surface which forms a of the roof of the corresponding nasal cavity. The frontal spine forms t of the septum of the nose; in front it articulates with the crest of the nasal s, behind with the lamina perpendicularis of the ethmoidal bone (fig. 322). he *temporal surface*, below and behind the temporal lines, forms the anterior of the temporal fossa, and gives origin to a part of the Temporalis le.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

The *cerebral or internal surface* (fig. 306) of the squama is concave; upper part of the middle line is a vertical groove, the *sagittal sulcus*, t of which unite below to form the *frontal crest*; the sulcus lodges the part of the superior sagittal sinus, while to its margins and to the fro the anterior part of the falx cerebri is attached. The crest ends below in notch which is converted into the *foramen cæcum* by articulation ethmoidal bone. The foramen cæcum varies in size in different skull often pervious; when this is so, it transmits a vein from the nose to the sagittal sinus. On either side of the middle line are depressions

Fig. 305.—The frontal bone. External aspect.

convolutions of the brain, and minute furrows for the anterior bran the middle meningeal vessels. Several small, irregular fossæ may b on either side of the sagittal sulcus, for the reception of arach granulations.

The *border of the squama* is thick, strongly serrated, bevelled expense of the cerebral surface above, where it rests upon the parietal and at the expense of the temporal surface on either side, where it the lateral pressure of the parietal bones; it is continued below triangular, rough surface, for articulation with the great wing of the sp bone.

The **orbital part** of the frontal bone consists of two thin triangular *plates*, which form the vaults of the orbits, and are separated from one by a wide gap, the *ethmoidal notch*.

The *orbital surface* (fig. 306) of each orbital plate is smooth and conc presents, laterally, under cover of the zygomatic process, a shallow dep the *lacrimal fossa*, for the lacrimal gland; below and behind the med of the supra-orbital margin, about midway between the supra-orbital and the frontolacrimal suture, is a small depression or spine, the *fovea t trochlearis*, for the attachment of the fibrocartilaginous pulley of the O oculi superior. The *cerebral surface* is convex and marked by dep

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ponding to the convolutions on the inferior surface of the frontal lobe brain, and by faint grooves for the meningeal branches of the ethmoidal s.

e *ethmoidal notch* (incisura ethmoidalis) (fig. 306) separates the two orbital ; it is quadrilateral, and filled, in the articulated skull, by the lamina a of the ethmoidal bone. On the margins of the notch are portions eral air-sinuses which complete the ethmoidal air-sinuses when the idal bone is in position. Two transverse grooves cross each margin of the ; they are converted into the *anterior and posterior ethmoidal canals* by

Fig. 306.—The frontal bone. Internal and inferior aspects.

thmoidal bone, and open on the medial wall of the orbit ; they transmit nterior and posterior ethmoidal nerves and vessels.

front of the ethmoidal notch, and lateral to the frontal spine, are the ngs of the *frontal air-sinuses* (fig. 307). These air-sinuses are two irregular ies, which extend backwards, upwards, and lateralwards for a variable nce between the tables of the frontal bone ; they are separated from one her by a thin bony septum, which is often deflected to one or other side of median plane, with the result that the sinuses are seldom symmetrical. mentary at birth, the frontal air-sinuses are usually fairly well-developed een the seventh and eighth years, but only reach their full size after rty. They vary in size in different persons, and are larger in men than men.* Occasionally they extend backwards in the roofs of the orbit

ogan Turner (*op. cit.*) gives the following measurements for an adult sinus of average size : 3·16 cm. ; breadth, 2·58 cm. ; depth from before backwards, 1·8 cm. Onodi (*op. cit.*) that in infants of from one to twelve months the height of the frontal sinus varies from m. to 8 mm., and its width from 2 mm. to 6 mm., and that in the eighth year of life the is from 14 mm. to 17 mm., and the width from 7 mm. to 9 mm.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cavities as far as the optic foramen. Each communicates with the meatus of the corresponding nasal cavity by means of a passage, the *frontonasal duct.*

FIG. 307.—Frontal air-sinuses. Anterior aspect. The left sinus is larger than the right and the septum between them is obliquely placed.

The *posterior borders of the orbital plates* are thin and serrated, and articulate with the small wings of the sphenoidal bone; the lateral part of each appears in the middle fossa of the skull between the great and small wings of the sphenoidal bone.

Structure.—The squama and the zygomatic process of the frontal bone are thick and consist of spongy substance contained between two compact laminæ; the spongy substance is absent in the parts occupied by the frontal air-sinuses. The orbital part, composed entirely of compact bone, is thin and translucent in its posterior two-thirds.

FIG. 308.—The frontal bone at birth. External aspect.

Ossification.—(fig. 308) The frontal bone is ossified in membrane from two primary centres which appear about the seventh or eighth week of fœtal life, one above each superciliary margin. From each of these centres ossification extends upwards into the corresponding half of the frontal bone and backwards to form the orbital plate. The frontal spine is ossified from two secondary centres, one on either side of the middle line. These secondary centres also appear in the orbital parts and zygomatic processes. At birth the bone consists of two halves separated by the frontal suture. The union of the pieces begins in the second year, and the frontal suture is obliterated, except at its lower part, by the eighth year.

THE ETHMOIDAL BONE (OS ETHMOIDALE)

The **ethmoidal bone** is cubical in shape, and exceedingly light. It is situated at the anterior part of the base of the cranium, and assists in forming the medial walls of the orbital cavities and the roofs and lateral walls of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cavities. It consists of four parts: a horizontal, perforated plate named mina cribrosa, a lamina perpendicularis, and two labyrinths or lateral s.

e **lamina cribrosa** of the ethmoidal bone (fig. 309) occupies the idal notch of the frontal bone and forms a part of the roofs of the nasal s. Projecting upwards from the median line of this lamina is a thick, h, triangular process, the *crista galli*, so called from its resemblance to 's comb. Its posterior border, long, thin, and curved, gives attachment falx cerebri. Its anterior border, short and thick, articulates with the l bone by two small projecting *alar processes* which complete the foramen n. Its sides are smooth, and sometimes bulging owing to the presence nall air-sinus in the interior. On either side of the crista galli, the lamina sa is narrow and depressed; it supports the olfactory bulb and is per- d by foramina for the passage of the olfactory nerves. The foramina middle part are small and transmit the nerves to the mucous membrane roof of the nasal cavity; those in the medial and lateral parts are larger former transmit the nerves to the mucous membrane on the upper part nasal septum, the latter erves to the mucous rane on the superior oncha. At the front the lamina cribrosa, her side of the crista s a small fissure which upied by a process of mater. Lateral to this is a foramen which its the anterior eth- l nerve to the nasal ; from this foramen ove runs backwards to nterior ethmoidal fora-

FIG. 309.—The ethmoidal bone. Superior aspect.

e **lamina perpendicu-** of the ethmoidal bone 310, 311), thin, flat, and hat quadrilateral in descends from the under e of the lamina cribrosa, orms the upper part of asal septum; it is generally deflected a little to one or other side. The *r border* articulates with the spine of the frontal bone and the crest of asal bones. The *posterior border* articulates with the sphenoidal crest and with the vomer below. The *superior border* is attached to the a cribrosa. The *inferior border* is thick, and serves for the attachment e cartilage of the septum of the nose. The surfaces of the lamina are h, except above, where numerous grooves and canals are seen; these rom the medial foramina in the lamina cribrosa and lodge filaments olfactory nerves.

ch **labyrinth** or **lateral mass** of the ethmoidal bone consists of a er of thin-walled *ethmoidal air-sinuses*, arranged in three groups, *anterior*, e, and *posterior*, and interposed between two vertical plates of bone; the l plate forms part of the medial wall of the orbit, the medial plate, part e lateral wall of the nasal cavity.* In the disarticulated bone many of ethmoidal air-sinuses are opened into, but in the articulated skull they are where closed, except at their apertures of communication with the nasal y. The *upper surface* of the labyrinth (fig. 309) presents a number of uses, the walls of which are completed, in the articulated skull, by the of the ethmoidal notch of the frontal bone. Crossing this surface are rooves which are converted into the *anterior and posterior ethmoidal canals*

me anatomists divide the ethmoidal air-sinuses into two groups, an *anterior*, comprising which open into the middle meatus, and a *posterior*, those which open into the superior of the nose.

e *medial surface* (fig. 315) is convex, perforated by numerous apertures, raversed by longitudinal grooves for the lodgment of vessels. The *lateral* e is concave (fig. 316), and forms part of the inferior meatus of the nasal . The *superior border* is thin and irregular, and may be divided into three ns: of these, the anterior articulates with the crista conchalis of the la, and the posterior with the crista conchalis of the palatine bone. The e portion presents three processes, which vary in size and form. Of these, *crimal process* is small and pointed and is situated at the junction of the or one-fourth with the posterior three-fourths of the bone: it articu- by its apex, with the descending process of the lacrimal bone (fig. 314), by its margins, with the edges of the nasolacrimal groove on the medial

15.—The right inferior nasal concha. Medial aspect.

FIG. 316.—The right inferior nasal concha. Lateral aspect.

e of the body of the maxilla, and thus assists in forming the canal for asolacrimal duct. Behind this process a thin plate, the *ethmoidal process*, ds to join the uncinate process of the ethmoid (fig. 314). From the e part of the superior border a thin lamella, the *maxillary process*, s downwards and lateralwards; it articulates with the maxilla and the llary process of the palatine bone, and forms a part of the medial wall of maxillary sinus (fig. 328). The *inferior border* is free, thick, and spongy ructure, more especially in the middle of the bone. Both *ends* are more s pointed, the posterior being the more tapered.

ssification.—The inferior nasal concha is ossified from one centre; this appears the fifth month of fœtal life in the maxilloturbinal cartilage which is the ved lower border of the lateral wall of the nasal capsule. It is detached from emainder of the nasal capsule during ossification.

THE LACRIMAL BONES (OSSA LACRIMALIA)

e **lacrimal bones**, the smallest and most fragile of the cranial bones, are ed at the front parts of the medial walls of the orbits (figs. 319, 328). Each mal bone has two surfaces and four borders.

lateral or orbital surface (fig. 317) is divided by a cal ridge, the *posterior lacrimal crest*. In front its crest is a vertical groove, the *lacrimal groove*. anterior border of this groove articulates with posterior border of the frontal process of the lla to complete the *lacrimal fossa* for the lodge- of the lacrimal sac. The medial wall of the mal groove is prolonged downwards under the e of the *descending process*. This process assists rming the bony canal for the nasolacrimal by articulating with the lips of the sulcus malis of the maxilla, and with the lacrimal ess of the inferior nasal concha. The portion d the crest is smooth, and forms a part of the al wall of the orbit. The crest, with a part of rbital surface immediately posterior to it, gives n to the lacrimal part of the Orbicularis oculi. crest ends below in a small hook, the *lacrimal hamulus*, which articulates the lacrimal tubercle of the maxilla and completes the upper orifice of the

FIG. 317.—The left lacrimal bone. Lateral aspect. (Enlarged.)

bony canal for the nasolacrimal duct ; the lacrimal hamulus somet as a separate piece, and is then called the *lesser lacrimal bone*. On th *nasal surface* is a vertical furrow, corresponding to the posterior lac on the lateral surface. The area in front of this furrow forms p middle meatus of the nose ; that behind the furrow articulates wi moidal bone, and completes some of the anterior ethmoidal air-sin *anterior border* of the lacrimal bone articulates with the frontal pro maxilla ; the *posterior border* with the lamina papyracea of the bone ; the *superior border* with the frontal bone. The posterior p *inferior border* articulates with the orbital plate of the maxilla.

FIG. 318.—A sketch showing how the medial wall of the nasolacrimal c completed by the articulation of the descending process of the lacrim with the lacrimal process of the inferior nasal concha. (After Whitna

Ossification.—The lacrimal bone is ossified from one centre, which about the twelfth week of fœtal life in the membrane covering the car nasal capsule.

THE NASAL BONES (OSSA NASALIA)

The **nasal bones** are two small oblong bones, varying in size and different individuals ; they are placed side by side between the frontal p of the maxillæ, and form, by their junction, 'the bridge' of the nose (f 356).

Each nasal bone has two surfaces and four borders. The *external* (fig. 320) is concavo-convex from above downwards, and convex from side ; it is covered by the Procerus and Compressor naris, and is pe near its centre by a foramen, for the transmission of a small vein. The *surface* (fig. 321) is concave from side to side, and is traversed from abo wards by a groove, the *ethmoidal sulcus*, which lodges the anterior et nerve. The *superior border*, thick and serrated, articulates with the nas of the frontal bone. The *inferior border*, thin and notched, gives att to the lateral cartilage of the nose. The *lateral border* articulates w frontal process of the maxilla. The *medial border*, thicker above than articulates with the opposite nasal bone, and is prolonged behind into a crest which forms a small part of the septum of the nose, and articulate above downwards, with the frontal spine, the lamina perpendicular ethmoidal bone, and the cartilage of the septum of the nose.

lage of the septum of the nose is lodged. As growth proceeds, the union of bony lamellæ extends upwards and forwards, and at the same time the inter-ng plate of cartilage undergoes absorption. By the age of puberty the lamellæ almost completely united, but evidence of the bilaminar origin of the bone is in the everted alæ of its upper border and the groove on its anterior border. to a certain stage the vomer is entirely derived from membrane, but 'it mes added to by the ossification of the hinder end of the anterior paraseptal lage.'* From this part of the ossified anterior paraseptal cartilage a plate of descends by the side of the primary part of the vomer, and fuses with it. vomeronasal cartilage of Jacobson is the persistent part of the anterior septal cartilage.*

THE SUTURAL BONES (OSSA SUTURARUM)

n addition to the usual centres of ossification of the cranial bones, others may occur e course of the sutures, giving rise to irregular, isolated, *sutural or Wormian* † *bones* 325). They occur most frequently in the course of the lambdoid suture, but are ionally seen at the fonticuli, especially the posterior. One, the *pterion ossicle*, some-exists between the sphenoidal angle of the parietal bone and the great wing of the oidal bone. They have a tendency to be more or less symmetrical on the two sides skull, and vary much in size. Their number is generally limited to two or three; ore than a hundred have been found in the skull of a hydrocephalic subject.

Fig. 325.—A sketch showing sutural bones in the lambdoid and sagittal sutures.

Sutural bones

pplied Anatomy.—An arrest in the ossifying process may give rise to deficiencies, gaps, ssures in the cranium, which are of importance from a medico-legal point of view, hey are liable to be mistaken for fractures. The fissures generally extend from the gins towards the centre of a bone, but the gaps may be found in the middle as well as he edges. In course of time they may become filled with thin laminæ of bone. In e instances, however, the gaps are due to absorption of bone already formed. This pecially so when they appear in the centre of a bone such as the parietal, the ossification ich has already been described as occurring in a regular manner radiating from two es. The condition is most commonly seen in very badly nourished children affected congenital syphilis, and is called *craniotabes*.

E. Fawcett, *Journal of Anatomy and Physiology*, vol. xlv.

Ole Worm, Professor of Anatomy at Copenhagen, 1624-1639, was erroneously supposed ave given the first detailed description of these bones.

THE FACIAL BONES (OSSA FACIEI)

The Maxillæ

The **maxillæ** are the largest bones of the face, excepting the mand form, by their union, the whole of the upper jaw (fig. 356). Each completing the roof of the mouth, the floor and lateral wall of the nose floor of the orbit; it also enters into the formation of the infra and pterygopalatine fossæ, and the inferior orbital and pterygo fissures.

Each **maxilla** consists of a body and four processes—zygomatic, alveolar, and palatine.

The **body** of the maxilla is somewhat pyramidal in shape. It surfaces,—anterior, infratemporal, orbital, and nasal—and encloses cavity, the **maxillary** air-sinus or antrum of Highmore.

The *anterior surface* (fig. 326) is directed forwards and lateralwar its lower part is a series of eminences (juga alveolaria) corresponding positions of the roots of the upper teeth. Just above those of the inciso is a depression, the *incisive fossa*, which gives origin to the Depressor se the alveolar border below the fossa a slip of the Orbicularis oris is at above and lateral to the fossa, the Nasalis arises. Lateral to the incisi is a larger and deeper depression, the *canine fossa*; it is separated f incisive fossa by the *canine eminence*, which corresponds to the socke canine tooth; the fossa gives origin to the Caninus. Above the cani is the *infra-orbital foramen*, the end of the infra-orbital canal; it tr the infra-orbital vessels and nerve. Above the foramen is a sharp marking the junction of the anterior and orbital surfaces. This bord a small part of the circumference of the base of the orbit, and gives o the orbital head of the Quadratus labii superioris. Medially, the anterior is limited by a deep concavity, the *nasal notch*; the margin of the not attachment to the Dilatator naris posterior, and ends below in a pointed which with the corresponding process of the opposite maxilla forms the *nasal spine.*

The *infratemporal surface* (fig. 326) is convex, directed backwar lateralwards, and forms the anterior wall of the infratemporal fossa separated from the anterior surface by the zygomatic process and by which runs upwards to that process from the socket of the first molar It is pierced near its centre by the apertures of two or three *alveolar* which transmit the posterior superior alveolar vessels and nerves. lower part of this surface is a round eminence, the *maxillary tuberosity* is rough for articulation with the pyramidal process of the palatine bone (fi it gives origin to a few fibres of the Pterygoideus internus, and in som articulates with the lateral pterygoid lamina of the sphenoidal bone. this is a smooth surface, which forms the anterior boundary of the p palatine fossa, and is grooved for the maxillary nerve; the groove nerve is directed lateralwards and slightly upwards, and is continuo the infra-orbital groove on the orbital surface.

The *orbital surface* (fig. 326) is smooth and triangular, and forms the part of the floor of the orbit. Its *medial border* presents anteriorly a the *lacrimal notch*, behind which it articulates from before backwards w lacrimal bone, the lamina papyracea of the ethmoidal bone, and the process of the palatine bone (fig. 328). Its *posterior border* is smoo rounded; it forms the lateral part of the lower margin of the inferior fissure, and its central part is notched by the commencement of the orbital groove. The *anterior border* forms a small part of the circum of the base of the orbit, and is continuous medially with the anterior l crest on the frontal process (p. 232). The *infra-orbital groove*, for the of the infra-orbital vessels and nerve, begins at the middle of the p border, where it is continuous with the groove near the upper edge of the

poral surface; it passes forwards and ends in the *infra-orbital canal*, which
s on the anterior surface of the bone just below the margin of the orbit.
he medial and front part of the orbital surface, and lateral to the lacrimal
ve, is a small depression, which gives origin to the Obliquus oculi inferior.
The *nasal surface* (fig. 327) presents in its upper and posterior part a large,
ular opening leading into the maxillary air-sinus. At the upper border
his aperture are some broken air-sinuses, which, in the articulated skull, are
ed by the ethmoidal and lacrimal bones. Below the opening into the
illary air-sinus is a smooth concave surface which forms part of the inferior
tus of the nasal cavity, and behind it is a rough surface for articulation
the vertical part of the palatine bone; this rough surface is traversed
groove, which begins near the middle of the posterior border, runs obliquely
nwards and forwards, and is converted into the *pterygopalatine canal* by
vertical part of the palatine bone and the pterygoid process of the sphenoidal

FIG. 326.—The left maxilla. Lateral aspect.

e. In front of the opening of the maxillary air-sinus is a deep groove, the
us lacrimalis, which constitutes about two-thirds of the circumference of the
olacrimal canal, the remaining one-third being formed by the descending
cess of the lacrimal bone and the lacrimal process of the inferior nasal
cha (fig. 318); this canal opens into the inferior meatus of the nose
314) and transmits the nasolacrimal duct. More anteriorly is an oblique
ge, the *crista conchalis*, for articulation with the inferior nasal concha. The
llow concavity below this ridge forms part of the inferior meatus of the
se, and the surface above the ridge part of the atrium of the middle meatus.
The **maxillary air-sinus** (*antrum of Highmore*) is a large pyramidal cavity
hin the body of the maxilla. Its walls are thin, and correspond to the
al, orbital, anterior, and infratemporal surfaces of the body of the bone.
apex, directed lateralwards, is formed by the zygomatic process; its *base*,
nasal wall, directed medialwards, is formed by the lateral wall of the nose,
presents, in the disarticulated bone, a large, irregular aperture communicat-
with the nasal cavity. In the articulated skull this aperture is much
uced in size by the following bones: the uncinate process of the ethmoidal
ne and the descending process of the lacrimal bone above, the maxillary
cess of the inferior nasal concha below, and the vertical part of the pala-
e bone behind (figs. 314, 328). The maxillary air-sinus communicates with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the middle meatus of the nose, generally by two small apertures, one
is usually closed, in the recent state, by mucous membrane. On the
wall are the *alveolar canals*, transmitting the posterior superior alveol
and nerves to the molar teeth; these canals occasionally project
into the maxillary air-sinus. The *floor* is formed by the alveolar p
the maxilla, and its lowest part is usually about 1·25 cm. below the
the floor of the nasal cavity. In a large proportion of cases radiat
of varying sizes spring from the floor of the sinus in the intervals
adjacent teeth; in some cases the floor is perforated by the fangs of
teeth.* The infra-orbital canal usually projects into the sinus a
marked ridge extending from the *roof* to the *anterior wall*. The siz
cavity varies in different skulls, and even on the two sides of the sam

FIG. 327.—The left maxilla. Medial aspect.

Applied Anatomy.—The extreme thinness of the walls of this cavity affords an
tion of the fact that a tumour growing from the maxillary air-sinus and encroachi
the adjacent parts may push up the floor of the orbit, and displace the eyeba
project into the nose; may protrude forwards on to the cheek; or may make
backwards into the infratemporal fossa, or downwards into the mouth.

The **zygomatic process** of the maxilla is a rough triangular emi
situated at the angle of separation of the anterior, infratemporal, and
surfaces. In front it forms part of the anterior surface of the body
bone; *behind*, it is concave, and continuous with the infratemporal s
above, it is rough and serrated for articulation with the zygomatic bone:
it presents a prominent arched border which separates the anterior fr
infratemporal surface.

The **frontal process** of the maxilla projects upwards and backwards b
the nasal and lacrimal bones (figs. 328, 353). Its *lateral surface* is divid
two parts by a vertical crest, the *anterior lacrimal crest*, which gives atta

* The number of teeth whose roots are in relation with the floor of the maxillary s
is variable. The sinus may extend so as to be in relation to all the teeth of the true maxil
the canine to the third molar.—(Salter.)

† Logan Turner (*op. cit.*) gives the following measurements for an adult sinus of avera
vertical height opposite first molar tooth, 3·5 cm.; transverse breadth, 2·5 cm.; and
posterior depth, 3·2 cm.

Digitized by Arya Samaj Foundation Chennai and eGangotri

he medial palpebral ligament, and is continuous below with the infra-orbital rin. At the junction of the crest with the orbital surface is a small tubercle, *lacrimal tubercle*, which serves as a guide to the position of the lacrimal The part in front of the anterior lacrimal crest is smooth, and merges w with the anterior surface of the body; it gives attachment to a portion e Orbicularis oculi, and to the angular head of the Quadratus labii superioris. part behind the anterior lacrimal crest is hollowed into a groove which ontinuous inferiorly with the sulcus lacrimalis on the nasal surface of the e, and posteriorly, in the articulated skull, with the lacrimal groove on lacrimal bone, the two grooves forming the *lacrimal fossa* for the lodgement he lacrimal sac.

FIG. 328.—The left maxillary air-sinus. Opened from the lateral side.

The *medial surface* of the frontal process forms a portion of the lateral wall he nasal cavity. A rough, uneven area at its upper part articulates with ethmoidal bone and closes in the anterior ethmoidal air-sinuses. Below rough area is an oblique ridge, the *crista ethmoidalis*, the posterior part which articulates with the middle nasal concha, while the anterior part ermed the *agger nasi*; the crista ethmoidalis forms the upper limit of the nm of the middle meatus of the nose. The *upper end* of the frontal process culates with the nasal notch of the frontal bone, the *anterior border* with nasal bone, and the *posterior border* with the lacrimal bone.

The **alveolar process** of the maxilla, thick and arched, is broader behind n in front, and excavated into cavities or alveoli for the reception of the ts of the teeth. These cavities are eight in number, and vary in size and th according to the teeth they contain. That for the canine tooth is the gest; those for the molars are the widest, and are subdivided into three or cavities by septa; those for the incisors and the second bicuspid are gle; that for the first bicuspid is sometimes divided into two. The Buccinator es from the outer surface of this process, as far forward as the first molar th. When the maxillæ are articulated with each other, their alveolar cesses together form the *alveolar arch*.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **palatine process** of the maxilla, thick and strong, is horiz projects medialwards from the nasal surface of the bone. It forms a co part of the floor of the nose and the roof of the mouth, and is much front than behind. Its *inferior surface* (fig. 329), concave, rough and forms, with the palatine process of the opposite bone, the anterior thre of the hard palate. It is perforated by numerous foramina for the the nutrient vessels, and presents depressions for the lodgement of the glands; it is channelled at the posterior part of its lateral border grooves which lodge the descending palatine vessels, and the anterior nerve. When the two maxillæ are articulated, a funnel-shaped ope *incisive foramen*, is seen in the middle line, immediately behind the inci

Fig. 329.—The bony palate and the alveolar arch. Inferior aspect.

In this opening the orifices of two lateral canals are visible; they are the *incisive canals* or *foramina of Stensen*; each leads upwards into the sponding nasal cavity and transmits the terminal branch of the greater p artery and the nasopalatine nerve. Occasionally there are two add apertures in the middle line; they are termed the *foramina of Scarp* when present transmit the nasopalatine nerves, the left passing throu anterior, and the right through the posterior foramen. On the under of the palatine process, a delicate suture, well seen in young skulls, may times be noticed extending lateralwards and forwards from the incisive fo to the interval between the lateral incisor and the canine teeth. The part in front of this suture constitutes the *premaxilla* or *os incisivum*, in most vertebrates forms an independent bone; it includes the whole th of the alveolus, the corresponding part of the floor of the nose and the a nasal spine, and contains the sockets of the incisor teeth. The *upper* of the palatine process is concave from side to side, smooth, and form greater part of the floor of the nasal cavity; close to the anterior part medial margin is the upper orifice of the incisive canal. The *lateral* of the process is fused with the rest of the bone. The *medial border*, in front than behind, is raised into a ridge, the *nasal crest*, which, wi

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

responding ridge of the opposite bone, forms a groove for the reception of vomer. The front part of this ridge rises to a considerable height, and is ed the *incisor crest* (fig. 327); it is prolonged forwards into a sharp pro- which, with the similar process of the opposite bone, forms the *anterior l spine*. The *posterior border* is serrated for articulation with the hori- al part of the palatine bone.

Ossification.—The maxilla is mainly developed in membrane. Mall* and cett† have shown that it is ossified from two centres, one for the maxilla proper one for the premaxilla. These centres appear at the end of the sixth week of l life, that for the maxilla proper commencing above the canine tooth-germ;

FIG. 330.—The right maxilla at birth. Lateral aspect.

FIG. 331.—The right maxilla at birth. Inferior aspect.

FIG. 332.—The right maxilla at birth. Medial aspect.

y unite at the end of the second or early in the third month, but the suture ween them (fig. 331) may persist on the palate until nearly middle life; the frontal ess of the bone is developed from both centres. The ossifying maxilla invades incorporates the paranasal process of the cartilaginous nasal capsule, a condition ch may account for the small islands of cartilage which are sometimes found in ossifying maxilla. The maxillary air-sinus appears as a shallow groove (fig. 332) the nasal surface of the bone about the fourth month of fœtal life, but does not ch its full size until after the second dentition. The infra-orbital vessels and ve lie for a time in an open groove in the floor of the orbit; the anterior part his groove is converted into the infra-orbital canal by a lamina of bone which ws from the lateral side of the groove.

CHANGES PRODUCED IN THE MAXILLA BY AGE

At birth the transverse and anteroposterior diameters of the maxilla are each greater n the vertical. The frontal process is well-marked, but the body of the bone consists of e more than the alveolar process, the tooth-sockets reaching almost to the floor of the it. The maxillary air-sinus is seen as a furrow on the lateral wall of the nose. In the lt the vertical diameter is the greatest, owing to the development of the alveolar pro- and the increase in size of the air-sinus. In old age, the bone reverts in some ure to the infantile condition: its height is diminished, and after the loss of the h the alveolar process is absorbed, and the lower part of the bone contracted and ced in thickness.

The Palatine Bones (Ossa Palatina)

The **palatine bones** are situated at the posterior part of the nasal between the maxillæ and the pterygoid processes of the sphenoidal bone (

Fig. 333.—The articulation of the left palatine bone with the left maxilla.

Each assists in forming the floor and lateral wall of the nasal cavity, t of the mouth, and the floor of the orbit; it enters into the formation pterygopalatine and pterygoid fossæ and the inferior orbital fissure.

The palatine bone somewhat resembles the letter L, and consist horizontal and a vertical part, and three outstanding processes—a pyramidal process, which is directed backwards, lateralwards, and down from the junction of the horizontal and vertical parts, and the orbit sphenoidal processes, which surmount the vertical part, and are sep by a deep notch, the sphenopalatine notch.

The **horizontal part** of the palatine bone (figs. 334, 335) is quadrilater has two surfaces and four borders. The *nasal surface*, concave from s side, forms the posterior part of the floor of the nasal cavity. The p *surface* forms, with the corresponding surface of the opposite bone, the po one-fourth of the hard palate; near its posterior margin is a curved The *posterior border* is thin and concave; to it, and to the palatine surface forwards as the curved ridge just mentioned, the expanded tendon of the veli palatini is attached. The medial end of the posterior border is p and, when united with that of the opposite bone, forms a projecting p the *posterior nasal spine*, for the attachment of the Musculus uvulæ *anterior border* is serrated, and articulates with the palatine process of the m The *lateral border* is united with the inferior border of the vertical part, grooved by the lower end of the pterygopalatine sulcus. The *medial* thick and serrated, articulates with the corresponding border of the o bone, and the opposed borders form a crest which articulates with the p part of the lower edge of the vomer, and is continuous anteriorly w nasal crest of the maxillæ.

The **vertical part** of the palatine bone (figs. 334, 335), thin and oblong form, has two surfaces and four borders.

The *nasal surface* exhibits at its lower part a broad, shallow dep which forms part of the inferior meatus of the nasal cavity. Immed

ve this is a horizontal ridge, the *crista conchalis*, for articulation with the rior nasal concha; still higher is a second broad, shallow depression, which ns part of the middle meatus, and is limited above by the *crista ethmoidalis*,

FIG. 334.—The left palatine bone. Medial aspect. (Enlarged.)

articulation with the middle nasal concha. Above the crista ethmoidalis narrow, horizontal groove, which forms part of the superior meatus.

The *maxillary surface* is rough and irregular throughout the greater part s extent, for articulation with the nasal surface of the maxilla; its upper posterior part is smooth and forms the medial wall of the pterygopalatine a; its front portion is also smooth and forms the posterior part of the ial wall of the maxillary air-sinus (fig. 328). On the posterior part of the illary surface is a deep vertical groove, the *pterygopalatine sulcus*, which the articulated skull is converted the *pterygopalatine canal* by the illa and the pterygoid process of sphenoidal bone; this canal trans- s the descending palatine vessels, the palatine nerves.

The *anterior border* is thin and gular; at the level of the crista chalis is a pointed projecting na, the *maxillary process*, which rected forwards below and behind maxillary process of the inferior l concha with which it articu- s and assists in forming the ial wall of the maxillary air- s (fig. 328). The *posterior border* 335) is serrated for articulation the medial pterygoid lamina of sphenoidal bone. This border is tinuous above with the sphenoidal cess; it expands below into the amidal process. The *superior* r supports the orbital process ront and the sphenoidal process nd. These processes are separ- d by the *sphenopalatine notch*, which is converted into the *sphenopalatine men* by the under surface of the body of the sphenoidal bone. In the culated skull this foramen leads from the pterygopalatine fossa into the

FIG. 335.—The left palatine bone. Posterior aspect. (Enlarged.)

posterior part of the superior meatus of the nose, and transmits the palatine vessels and the posterior superior nasal nerves. The *infer* is fused with the lateral border of the horizontal part, and in the pyramidal process is grooved by the lower end of the pteryg sulcus.

The **pyramidal process** (tuberosity) of the palatine bone projects ba lateralwards, and downwards from the junction of the horizontal and parts of the bone, and fits into the angular interval between the lower the pterygoid laminæ. On its *posterior surface* is a smooth, grooved, tr area, limited on either side by a rough articular furrow. The furrows a with the pterygoid laminæ, while the grooved triangular area comp lower part of the pterygoid fossa and gives origin to some fibres of th goideus internus. The anterior part of the *lateral surface* is rough for tion with the maxillary tuberosity; the posterior part consists of a triangular area which appears, in the articulated skull, at the lower the infratemporal fossa between the maxillary tuberosity and the pterygoid lamina (fig. 328). In the *base* or *inferior surface* of the py process, close to its union with the horizontal part of the bone, are th *palatine foramina* for the transmission of the middle and posterior nerves (fig. 329).

The **orbital process** of the palatine bone (figs. 334, 335) is directed up and lateralwards from the front of the vertical part, to which it is joine constricted neck. It encloses an air-sinus, and presents three articu two non-articular surfaces. The articular surfaces are: (1) the *ant maxillary*, of an oblong form, is directed forwards, lateralwards, and dow and articulates with the maxilla; (2) the *posterior* or *sphenoidal*, backwards, upwards, and medialwards, presents the opening of the ai which usually communicates with the sphenoidal air-sinus; the ma the opening articulate with the sphenoidal concha; (3) the *medial* or *eth* directed medialwards and forwards, articulates with the labyrinth ethmoidal bone. In some cases, the air-sinus opens on this surface an communicates with the posterior ethmoidal air-sinuses; more rarely i on the ethmoidal and sphenoidal surfaces, and then communicates w posterior ethmoidal air-sinuses, and the sphenoidal air-sinus. The non-a surfaces are: (1) the *superior* or *orbital*, triangular in shape, is directed u and lateralwards, and forms the posterior part of the floor of the orbi (2) the *lateral*, of an oblong form, is directed towards the pterygop fossa, and is separated from the orbital surface by a rounded border forms the medial part of the lower margin of the inferior orbital fissu the lower part of this surface is a groove, directed lateralwards and up which lodges the maxillary nerve and is continuous with the transverse on the upper part of the infratemporal surface of the maxilla (p. 230) border between the lateral and posterior surfaces is prolonged downw the anterior boundary of the sphenopalatine notch.

The **sphenoidal process** of the palatine bone (figs. 334, 335) is a compressed plate, smaller and on a lower level than the orbital process directed upwards and medialwards. Its *superior surface* articulates wi under surface of the sphenoidal concha and the root of the medial pte lamina; it presents a groove which contributes to the formation of the p geal canal. The *inferomedial surface* is concave, and forms a small part roof and lateral wall of the nasal cavity. The posterior part of the *lateral* articulates with the medial pterygoid lamina; the anterior part is smoo forms a portion of the medial wall of the pterygopalatine fossa. The p *border* is rough and articulates with the vaginal process of the medial pte lamina. The *anterior border* forms the posterior boundary of the sphenop notch. The *medial border* articulates with the ala of the vomer.

The orbital and sphenoidal processes are separated from one anot the *sphenopalatine notch* which is converted into the sphenopalatine fo by the under surface of the body of the sphenoidal bone; sometimes th processes are united by a spicule of bone which converts the notch i foramen.

Ossification.—The palatine bone is ossified in membrane from one centre, appears during the eighth week of fœtal life in the vertical part of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

n this point ossification spreads upwards into the orbital and sphenoidal pro-
es, medialwards into the horizontal part, and downwards into the pyramidal
ess.
At the time of birth the height of the vertical part is about equal to the transverse
h of the horizontal part, whereas in the adult it measures nearly twice as much.

The Zygomatic Bones (Ossa Zygomatica)

The **zygomatic or malar bones** are situated at the upper and lateral parts
he face. Each forms the prominence of the cheek, part of the lateral wall
floor of the orbit, and parts of the temporal and infratemporal fossæ
336).
The zygomatic bone is quadrangular in shape and has two surfaces, four
ers, and four processes.

Fig. 336.—The left zygomatic bone *in situ*.

The *malar surface* (figs. 336, 337), directed lateralwards and forwards, is
vex and is perforated near its orbital border by the *zygomaticofacial foramen*
the passage of the zygomaticofacial nerve and vessels; below this foramen
slight elevation, which gives origin to the Zygomaticus. The *temporal*
face (fig. 338), directed medialwards and backwards, is concave, presenting
eriorly a rough, triangular area, for articulation with the maxilla, and
eriorly a smooth, concave surface, the upper part of which forms the
erior boundary of the temporal fossa, the lower, a part of the infratemporal
a. Near the posterior edge of the rough triangular area is the *zygomatico-*
poral foramen for the transmission of the zygomaticotemporal nerve.
The *anterosuperior or orbital border* is smooth, concave, and forms a con-
erable part of the circumference of the base of the orbit. The *antero-inferior*
maxillary border is rough, and articulates with the maxilla; near the orbital
rgin it gives origin to the zygomatic head of the Quadratus labii superioris.
e *posterosuperior or temporal border*, curved like an italic letter *f*, is continuous
re with the temporal line on the frontal bone, and below with the upper
der of the zygomatic arch; the temporal fascia is attached to it. The
ntero-inferior or zygomatic border affords attachment by its rough edge to
Masseter.
The *frontosphenoidal process* is thick and serrated, and articulates with the
omatic process of the frontal bone. On its orbital surface, just within the

temporal and infratemporal fossæ. Its *anterior margin*, smooth and ro is part of the circumference of the base of the orbit. Its *superior* rough, and directed horizontally, articulates with the frontal bone the zygomatic process. Its *posterior margin* is serrated for articulatio the great wing of the sphenoidal bone above, and the orbital surface maxilla below. Between these two serrated portions there is usually a concave, non-articular part which forms the anterior boundary of the orbital fissure. This non-articular part is sometimes absent, and the fis then completed by the junction of the maxilla and the sphenoidal bone, the interposition of a small sutural bone in the angular interval between

The *infra-orbital process* is pointed and articulates with the maxilla, the infra-orbital foramen.

The *temporal process* is directed backwards and ends in an oblique, s margin which articulates with the zygomatic process of the temporal bo

Ossification.—The zygomatic bone is ossified from one centre which about the eighth week of fœtal life. The bone is sometimes divided by a ho suture into an upper larger, and a lower smaller division.

THE MANDIBLE (MANDIBULA)

The **mandible**, the largest and strongest bone of the face, consis curved, horizontal portion, the *body*, from the ends of which two perpen portions, the *rami*, project upwards.

* S. E. Whitnall, *The Anatomy of the Human Orbit*, 1921.—The structures attache tubercle are: (1) the "check ligament" of the Rectus lateralis; (2) part of the ap of the Levator palpebræ superioris; (3) the suspensory ligament of the eyeball; and lateral palpebral ligament.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The body of the mandible is curved somewhat like a horseshoe, and has two faces and two borders. The *external surface* (fig. 339) is marked in the upper t of the median line by a faint ridge, indicating the *symphysis* or junction of two pieces of which the bone is composed at an early period of life. This e divides below and encloses a triangular eminence, the *mental protuberance*, base of which is depressed in the centre but raised on either side to form *mental tubercle*. On either side of the ridge, just below the incisor teeth, he *incisive fossa*, which gives origin to the Mentalis and to a small portion he Orbicularis oris. Below the second premolar tooth, and about midway ween the upper and lower borders of the body, is the *mental foramen*, for

FIG. 339.—The left half of the mandible. Lateral aspect.

exit of the mental vessels and nerve. Running backwards and upwards m the mental tubercle is a faint ridge, the *oblique line*, which is continuous h the anterior border of the ramus; the Quadratus labii inferioris and angularis are attached to it, and the Platysma below it.

The *internal surface* (fig. 340) is concave from side to side. Near the lower of the symphysis is a pair of laterally placed spines, termed the *mental nes*, which give origin to the Genioglossi. Immediately below these is a ond pair of spines, or more frequently a median ridge or impression, for the gins of the Geniohyoidei. In some bones the mental spines are fused to form ingle eminence; in others they are absent, and their position is indicated rely by an irregularity of the surface. Above the mental spines a median amen and furrow are sometimes present; they mark the line of union of the ves of the bone. Below the mental spines, on either side of the middle line, an oval depression, the *digastric fossa*, for the attachment of the anterior ly of the Digastricus. Extending upwards and backwards on either side from e lower part of the symphysis to a point behind the last molar tooth is the *lohyoid line* which gives origin to the Mylohyoideus; the posterior part this line, near the alveolar margin, gives attachment to a small part of the nstrictor pharyngis superior, and to the pterygomandibular raphe. Above e anterior part of this line is a smooth triangular area against which the blingual gland rests, and below the posterior part, an oval fossa for a part he submaxillary gland.

The *alveolar part* or upper portion of the body is hollowed into sixteenities or alveoli, for the reception of the roots of the teeth; these cavities y in depth and size, and are single or subdivided by septa, according to teeth which they contain. From the external surface of the alveolar part Buccinator takes origin as far forwards as the first molar tooth. The

inferior border or *base* of the mandible is rounded, and is thicker in fr behind: at the point where it is continuous with the lower border of th a shallow groove, for the external maxillary artery, may be present.

The **ramus** of the mandible is quadrilateral in shape, and has two four borders, and two processes. The *lateral surface* (fig. 339) is marked by oblique ridges at its lower part; it gives attachment th nearly the whole of its extent to the Masseter. The *medial surface* presents about its centre the *mandibular foramen*, which transmits the

Fig. 340.—The left half of the mandible. Medial aspect.

alveolar vessels and nerve. The foramen is overlapped in front by a tri process, the *lingula mandibulæ*, to the margins of which the sphenoman ligament is attached. Behind the lingula is a notch from which the my *groove* runs obliquely downwards and forwards; this groove lodges the hyoid vessels and nerve. Behind the groove is a rough surface for the in of the Pterygoideus internus. Into the anterosuperior part of the surface a portion of the Temporalis is inserted. The *lower border* of the is thick, straight, and continuous with the inferior border of the body bone. At its junction with the posterior border is the *angle* of the ma which may be either inverted or everted, and is marked by rough, oblique on either surface, for the insertion of the Masseter laterally, and the Pterg internus medially; the stylomandibular ligament is attached to the between these muscles. The *border*, thin above and thick is continuous with the oblique The *posterior border*, thick, and rounded, is covered b parotid gland. The *upper* is surmounted by two pro the *coronoid* in front and th *dyloid* behind; these are sep by a deep concavity, the *bular notch*, which transmi masseteric nerve and vessels.

Fig. 341.—The right half of the mandible of a human embryo 24 mm. long. Lateral aspect. (From a model by Low.)

The *coronoid process* of mandible is a thin, tria eminence, which is flattened side to side. Its *anterior border* is convex and is continuous below wi anterior border of the ramus; its *posterior border* is concave and form anterior boundary of the mandibular notch. Its *lateral surface* is smoot

rds insertion to the Masseter and Temporalis. Its *medial surface* gives rtion to the Temporalis, and presents a ridge which begins near the apex he process and runs downwards and forwards to the medial side of the molar tooth. Between this ridge and the anterior border is a grooved gular area, the upper part of which gives attachment to the Temporalis, lower part to some fibres of the Buccinator.

The *condyloid process* of the mandible is thicker than the coronoid process, consists of two portions; the condyle, and the constricted neck which orts it. The *condyle* articulates with the articular disc of the temporo-dibular joint; it is convex from before backwards and from side to side, its articular surface extends lower on the posterior than on the anterior ace. The long axis of the condyle is directed medialwards and slightly wards, and if prolonged to the middle line will meet that of the opposite yle near the anterior gin of the foramen num. At the lateral emity of the con- is a small tubercle the attachment of mandibular liga- The *neck* is ened from before kwards, and strength- d by ridges which end from the sides the lateral part of front of the condyle. posterior surface is vex; on its anterior surface is a depression, the *pterygoid fovea*, for the chment of the Pterygoideus externus.

FIG. 342.—The right half of the mandible of a human embryo 24 mm. long. Medial aspect. (From a model by Low.)

The *mandibular canal* runs from the mandibular foramen obliquely down- rds and forwards in the ramus, and then horizontally forwards in the body eath the alveoli, with which it communicates by small openings. It contains inferior alveolar vessels and nerve, from which branches enter the roots of teeth. Between the roots of the first and second premolar teeth the ndibular canal divides into the *mental* and *incisive canals*; the mental al runs upwards, backwards and lateralwards and ends at the mental men; the incisive canal is continued forward below the incisor teeth.

Ossification.—The mandible is ossified in the fibrous membrane covering the er surfaces of Meckel's cartilages. These two cartilages, a right and a left, the cartilaginous bar of the mandibular arch (p. 76). Their dorsal or cranial are connected with the cartilaginous ear-capsules, and their ventral ends joined to one another by mesodermal tissue. They run forwards immediately ow the mandibular condyles and then, bending downwards, lie in a groove near lower border of the bone; in front of the canine teeth they incline upwards he symphysis. From the proximal end of each cartilage the malleus and incus, of the three ossicles of the middle ear, are developed; the next succeeding tion, as far as the lingula of the mandible, is replaced by fibrous tissue which ns the sphenomandibular ligament. Between the lingula and the canine tooth cartilage disappears, whilst the portion of it below and behind the incisor th is ossified and incorporated with this part of the mandible.

Ossification takes place in the membrane covering the outer surfaces of Meckel's tilages (figs. 341 to 344), and each half of the bone is formed from one centre* ich appears, near the mental foramen, about the sixth week of fœtal life. By tenth week the portion of Meckel's cartilage which lies below and behind the isor teeth is surrounded and invaded by the membrane-bone. Somewhat later, essory pieces of cartilage make their appearance—viz. a wedge-shaped piece in condyloid process and extending downwards through the ramus; a small patch g the anterior border of the coronoid process; and smaller nodules in the front t of both alveolar walls and along the front of the lower border of the bone.

* A. Low, *Proceedings of the Anatomical and Anthropological Society of the University of Aberdeen*, 5, and *Journal of Anatomy and Physiology*, vol. xliv., and E. Fawcett, *Journal of the American dical Association*, September 3, 1905.

formed in the human mandible by an ingrowth from the main mass of the At birth the bone consists of two parts, united by a fibrous symphysis, in ossification takes place during the first year.

THE CHANGES PRODUCED IN THE MANDIBLE BY AGE

At birth (fig. 345) the body of the bone is a mere shell, containing on either sid sockets of the deciduous teeth, imperfectly partitioned off from one another. mandibular canal runs near the lower border of the bone, and the mental foramen beneath the socket of the first deciduous molar tooth. The angle is obtuse (175°), an condyloid portion is nearly in line with the body. The coronoid process is relat large, and projects above the level of the condyle.

After birth (fig. 346) the two segments of the bone become joined at the sym from below upwards, in the first year; but a trace of separation may be visible beginning of the second year, near the alveolar margin. The body elongates, but especially behind the mental foramen to provide space for the three additional developed in this part. The depth of the body increases by growth of the alveolar of the bone, to afford room for the roots of the teeth, and by thickening of the alveolar portion. After the second dentition, the mandibular canal is situated just the level of the mylohyoid line, and the mental foramen occupies the position usual in the adult. By the fourth year the angle is reduced to about 140°.

In the adult (fig. 347) the alveolar and subalveolar portions of the body are of equal depth. The mental foramen opens midway between the upper and lower borde the bone, and the mandibular canal runs nearly parallel with the mylohyoid line. ramus is almost vertical in direction, the angle measuring from 110° to 120°.

In old age (fig. 348) the bone is reduced in size, for with the loss of the teeth alveolar process is absorbed, and, consequently, the mandibular canal and the m foramen are close to the alveolar border. The ramus is oblique in direction, the measures about 140°, and the neck of the condyle is more or less bent backwards.

The Hyoid Bone (Os Hyoideum)

The **hyoid bone** (fig. 349) is U-shaped, and is suspended from the the styloid processes of the temporal bones by the stylohyoid ligame consists of a body, two greater and two lesser cornua.

The **body** or central part of the hyoid bone is of a quadrilateral fo *anterior surface* is convex and directed forwards and upwards. Its up is crossed by a well-marked ridge which has a slight downward co and in many cases a vertical median ridge divides the body into lateral The portion of the vertical ridge above the transverse line is present in a r of specimens, but that below the transverse line is rarely seen. The surface gives insertion to the Geniohyoideus in the greater part of its both above and below the transverse ridge; a portion of the origin Hyoglossus notches the lateral margin of the Geniohyoideus attachment. the transverse ridge the Mylohyoideus, Sternohyoideus, and Omoh are inserted. The *posterior surface* is smooth, concave, directed bac

Fig. 349.—The hyoid bone. Antero-superior aspect.

Fig. 350.—A sketch of left half of hyoid bone to show the musc attachments.

and downwards, and separated from the epiglottis by the hyoth membrane and a quantity of loose areolar tissue; a bursa interven tween the bone and the membrane. The *superior border* is rounded, and attachment to the hyothyreoid membrane and to some aponeurotic fi the Genioglossus. The *inferior border* affords insertion medially to the S hyoideus and laterally to the Omohyoideus and occasionally a portion o Thyreohyoideus. It also gives attachment to the Levator glandulæ thyre when this muscle is present. In early life the *lateral borders* of the bo connected to the greater cornua by synchondroses, but after middle lif are usually united by bone.

The **greater cornua** of the hyoid bone project backwards from the borders of the body; they are flattened from above downwards and di in size from before backwards. Each cornua ends posteriorly in a tube which the lateral hyothyreoid ligament is fixed. The *upper surface* is close to its lateral border, for muscular attachments: the largest of the the origins of the Hyoglossus and Constrictor pharyngis medius which along the whole length of the cornu; the Digastricus and Stylohyoideu small insertions in front of these, near the junction of the body with the To the *medial border* the hyothyreoid membrane is attached, while the an half of the *lateral border* gives insertion to the Thyreohyoideus.

The **lesser cornua** of the hyoid bone are two small, conical emin attached by their bases at the angles of junction of the body and greater co They are connected to the body of the bone by fibrous tissue and occasio to the greater cornua by diarthrodial joints, which usually persist throu life, but occasionally become ankylosed.

The lesser cornua are situated in the line of the transverse ridge on the

appear to be morphological continuations of it. The apex of each cornu attachment to the stylohyoid ligament †; the Chondroglossus rises from medial side of the base.

Ossification.—The hyoid bone is developed from the cartilages of the second third branchial or visceral arches—the lesser cornua from the second, the er cornua from the third, and the body from the fused ventral ends of both s (p. 77). It is ossified from six centres: two for the body, and one for each n. Ossification commences in the greater cornua towards the end of fœtal in the body before or shortly after birth, and in the lesser cornua during the or second year, or later.

THE EXTERIOR OF THE SKULL

he skull as a whole may be viewed from above (norma verticalis), from w (norma basalis), from the side (norma lateralis), from behind (norma vitalis), or from the front (norma frontalis).

Norma Verticalis

When viewed from above, the outline of the skull varies greatly in different imens; in some it is more or less oval, in others more nearly circular. The face is traversed by three sutures, viz.: (1) the coronal, nearly transverse in ction, between the frontal and parietal bones; (2) the sagittal, in the dian plane, between the parietal bones, and deeply serrated in its anterior thirds; and (3) the upper part of the lambdoid, between the occipital and etal bones. The point of junction of the sagittal and coronal sutures med the bregma, that of the sagittal and lambdoid sutures, the lambda; indicate respectively the positions of the anterior and posterior fonticuli e fœtal skull. On either side of the sagittal suture are the parietal tubero- or eminence and the parietal foramen—the latter, however, is frequently nt on one or both sides. The skull is often somewhat flattened in the hbourhood of the parietal foramina, and the term obelion is applied to that t of the sagittal suture which is on a level with the foramina. At the t of the skull are the frontal tuberosities or eminences; below these are superciliary arches, joined to one another by the elevation of the glabella. ediately above the glabella the remains of the frontal suture may be seen; ancy this suture divides the frontal bone into two parts, a condition which is in about 9 per cent. of skulls. Passing backwards and upwards from zygomatic processes of the frontal bone are the temporal lines, which mark upper limits of the temporal fossæ. The zygomatic arches may or may not een projecting beyond the anterior portions of these lines.

Norma Basalis (Basis Cranii Externa) (figs. 351, 352)

The external surface of the base of the skull, exclusive of the mandible, is nded in front by the incisor teeth in the maxillæ; behind, by the superior al lines of the occipital bone; and laterally by the alveolar arch, the lower der of the zygomatic bone, the zygomatic arch and an imaginary line drawn n this arch to the mastoid process of the temporal bone and the superior al line of the occipital bone. The anterior part or hard palate projects w the level of the rest of the surface, and is bounded in front and laterally by alveolar arch containing the sixteen teeth of the maxillæ (fig. 329). Immedi- behind the incisor teeth is the incisive foramen. In this foramen are ateral apertures, the openings of the incisive canals (foramina of Stensen); of these leads upwards into the corresponding nasal cavity and transmits

bone and the vaginal process of the medial pterygoid lamina, below horizontal part of the palatine bone, and laterally by the medial pl lamina. At the superior border of the vomer are the expanded al bone, which receive between them the rostrum of the sphenoidal b articulate laterally with the sphenoidal processes of the palatine bone vaginal processes of the medial pterygoid laminæ. Below the vaginal are the pharyngeal canals. The medial pterygoid lamina is long and lateral to its upper part is the scaphoid fossa, for the origin of the Te palatini; this muscle descends in contact with the medial surface of the and its tendon turns round the hamulus at the lower end of the lam the upper end of the medial pterygoid lamina is the pterygoid tuber immediately above this tubercle, the posterior end of the pterygoi The lateral pterygoid lamina is broad; its lateral surface forms the boundary of the infratemporal fossa, and gives origin to the lower hea Pterygoideus externus. Its medial surface forms the lateral wall of th goid fossa, and gives origin to the greater part of the Pterygoideus inte

Behind the choanæ are the posterior part of the body of the sphenoi and the basilar portion of the occipital bone; near the centre of the the pharyngeal tubercle for the attachment of the fibrous raphe of the p and on either side of the middle line are depressions for the inser the Longus capitis and Rectus capitis anterior. Behind the upper end lateral pterygoid lamina is the foramen ovale, for the transmission mandibular nerve, the accessory meningeal artery, and sometimes th superficial petrosal nerve; behind the foramen ovale are the foramen sp and the spina angularis of the sphenoidal bone; the former transm middle meningeal artery and the nervus spinosus, the latter gives atta to the sphenomandibular ligament and to a part of the Tensor veli p Lateral to the spina angularis is the mandibular fossa, divided into tw by the petrotympanic fissure; the anterior portion of the fossa, c smooth and bounded in front by the articular tubercle, articulates w articular disc of the mandibular joint; the posterior portion, bounded by the tympanic part of the temporal bone, is sometimes occupied by of the parotid gland. Emerging from the vagina processus styloide tympanic part of the temporal bone is the styloid process; and bet upper end of this process is the stylomastoid foramen, for the exit of th nerve, and entrance of the stylomastoid artery. Lateral to the stylo foramen, between the tympanic part and the mastoid process, is the ty mastoid fissure, which gives exit to the auricular branch of the vagu Medial to the mastoid process is the mastoid notch (digastric fossa) posterior belly of the Digastricus, and medial to the mastoid notch, the for the occipital artery. At the base of the medial pterygoid lamina foramen lacerum, bounded anteriorly by the great wing of the sphenoid posteriorly and laterally by the apex of the petrous portion of the te bone, and medially by the body of the sphenoidal bone and the basilar of the occipital bone; it presents in front, the posterior orifice of the pt canal; behind, the superior aperture of the carotid canal. In the recen the lower part of the foramen lacerum is filled up by a fibrocartilaginous on the upper surface of which the internal carotid artery rests. Betw petrous part of the temporal bone and the great wing of the sphenoid is the sulcus tubæ auditivæ. This sulcus, directed lateralwards and back lodges and gives attachment to the cartilaginous part of the auditory and is continuous behind with the semicanalis tubæ auditivæ in the te bone. In the floor of this sulcus is the petrosphenoidal fissure, occup the recent condition, by a plate of cartilage. Behind this fissure is the surface of the petrous portion of the temporal bone, presenting, near its a quadrilateral rough surface, part of which gives origin to the Levat palatini; lateral and posterior to this surface is the inferior orifice of the canal, and medial to this orifice, the depression leading to the aqua cochleæ. Behind the inferior orifice of the carotid canal is the jugular fo formed in front and laterally by the petrous portion of the temporal behind and medially by the occipital bone; it is generally larger on th than on the left side of the skull. The anterior part of the jugular fo transmits the inferior petrosal sinus; the intermediate, the glossopharyn

and accessory nerves; the posterior, the transverse sinus and some ngeal branches from the occipital and ascending pharyngeal arteries. On dge of bone between the inferior orifice of the carotid canal and the jugular en is the inferior tympanic canaliculus for the passage of the tympanic h of the glossopharyngeal nerve, and in the lateral part of the jugular en, near the root of the styloid process, is the mastoid canaliculus for the ge of the auricular branch of the vagus nerve. Running from the jugular en to the foramen lacerum is the petro-occipital fissure, occupied, in the t state, by a plate of cartilage. Behind the basilar portion of the occipital is the foramen magnum which transmits the medulla oblongata and its branes, the spinal parts of the accessory nerves, the vertebral arteries, nterior and posterior spinal arteries, and the ligaments connecting the ital bone with the epistropheus or axis vertebra. Lateral to the anterior of the foramen magnum are the occipital condyles for articulation with las vertebra; the medial side of each condyle is rough for the attachment e alar ligament. Lateral to the condyle is the jugular process of the ital bone, which gives attachment to the Rectus capitis lateralis. In front e condyle is the hypoglossal canal for the passage of the hypoglossal and a meningeal artery. Behind the condyle is the condyloid fossa, t is sometimes perforated by the condyloid canal for the transmission of n from the transverse sinus. Behind the foramen magnum is the n nuchal line, ending above at the external occipital protuberance; on side are the superior and inferior nuchal lines, which, with the surfaces ne between them, are rough for the attachment of the muscles enumerated 196.

Norma Lateralis (fig. 353)

When viewed from the side the skull is seen to consist of the cranium above behind, and the face below and in front. The cranium is somewhat ovoid hape, but its contour varies in different cases, and depends largely on the th and height of the skull and on the degree of prominence of the superciliary es and frontal tuberosities. Entering into its formation are the frontal, etal, occipital, temporal, and sphenoidal bones. These bones are joined e another by the coronal, sphenofrontal, sphenoparietal, sphenosquamosal, mosal, parietomastoid and lambdoid sutures. The sphenoparietal suture es in length in different skulls, and is absent in those cases where the tal bone articulates with the temporal squama; the posterior end of the enoparietal suture is named the pterion. The squamosal suture arches wards from the pterion and connects the temporal squama with the lower er of the parietal bone; it is continuous behind with the short, nearly ontal parietomastoid suture which unites the mastoid process of the ral bone with the mastoid angle of the parietal bone. Extending across cranium are the coronal and lambdoid sutures; the former connects the tal and parietal bones; the latter, the occipital and parietal bones. The bdoid suture is continuous below with the occipitomastoid suture between occipital bone and the mastoid portion of the temporal bone; in or near latter suture is the mastoid foramen which transmits an emissary vein. Immediately above the orbital margin is the superciliary arch, and, at a er level, the frontal tuberosity. Near the centre of the parietal bone is parietal tuberosity. Posteriorly is the external occipital protuberance, n which the superior nuchal line may be followed to the mastoid process. temporal lines arch across the side of the cranium and mark the upper it of the temporal fossa.

The *temporal fossa* is bounded above and behind by the temporal lines, ich extend from the zygomatic process of the frontal bone upwards and wards across the frontal and parietal bones, and then curve downwards forwards to the temporal bone to become continuous with the supra- oid crest and the posterior root of the zygomatic arch. The temporal a is bounded in front by the frontal and zygomatic bones; opening on latter is the zygomaticotemporal foramen. Laterally the fossa is limited the zygomatic arch; below, it is separated from the infratemporal fossa the infratemporal crest on the great wing of the sphenoidal bone, and by a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ridge which runs backwards from this crest across the temporal squa
anterior root of the zygomatic process. The floor of the fossa, deepl
in front, is formed by the zygomatic, frontal, parietal, sphenoidal, and
bones. It is traversed by vascular furrows: one, usually well mar
upwards above the opening of the external acoustic meatus, and l
middle temporal artery. Two others, frequently indistinct, may be
on the anterior part of the floor, and are for the anterior and poste
temporal arteries. The temporal fossa contains the Temporalis mu
its vessels and nerves, together with the zygomaticotemporal nerve.

Fig. 353.—The skull. Lateral aspect. (Norma lateralis.)

The *zygomatic arch* is formed by the union of the zygomatic process temporal bone with the temporal process of the zygomatic bone; the of the Temporalis descends on the medial side of the arch to gain ins into the coronoid process of the mandible. The zygomatic process temporal bone arises by two roots, an anterior, directed inwards in fr the mandibular fossa, where it expands to form the articular tubercle. posterior which runs backwards above the opening of the external a meatus and is continuous with the temporal line. The upper border zygomatic arch gives attachment to the temporal fascia; the lower and medial surface of the arch give origin to the Masseter.

Below the posterior root of the zygomatic arch is the porus ac externus, to the circumference of which the cartilaginous segment external acoustic meatus is attached. The small triangular area be the supramastoid crest and the posterosuperior part of the porus acu externus is termed the suprameatal triangle, and on the anterior bor this triangle, the suprameatal spine is sometimes seen. Between the tym

nd the articular tubercle is the mandibular fossa; behind the fossa yloid process extends downwards and forwards for a variable distance; es attachment to the Styloglossus, Stylohyoideus, and Stylopharyngeus es, and to the stylohyoid and stylomandibular ligaments. Projecting wards behind the porus acusticus externus is the mastoid process, to the surface of which the Sternoc leidomastoideus, Splenius capitis, and ssimus capitis are attached.

e *infratemporal fossa* (fig. 351) is an irregularly shaped space, situated l to the zygomatic arch and the coronoid process of the mandible. It nded in front by the infratemporal surface of the maxilla, and by a which ascends from the socket of the first molar tooth; behind, by the lar tubercle of the temporal bone and the spina angularis of the sphenoidal

Fig. 354.—The left infratemporal fossa.

; above, by the great wing of the sphenoidal bone below the infratemporal , and a small triangular part of the temporal squama in front of the arti- r tubercle; below, by the alveolar border of the maxilla; medially, by ateral pterygoid lamina. It contains the lower part of the Temporalis, Pterygoidei internus et externus, the internal maxillary vessels, and the dibular and maxillary nerves. The foramen ovale and foramen spinosum on its roof, and the alveolar canals, on its anterior wall. At the upper medial part of the fossa are two fissures, which meet at a right angle, the zontal limb being the inferior orbital fissure, and the vertical limb the ygomaxillary fissure.

The *inferior orbital fissure* (sphenomaxillary fissure), nearly horizontal in ction, opens into the lateral and posterior part of the orbit. It is bounded by the lower border of the orbital surface of the great wing of the noidal bone; below, by the lateral border of the orbital surface of the illa and the orbital process of the palatine bone; laterally, by a small part e zygomatic bone *; medially, it joins at right angles with the pterygo-

* In from 35 to 40 per cent. of skulls the maxilla and the sphenoidal bone articulate with ther at the lateral end of this fissure, and exclude the zygomatic bone from it.

Fig. 355.—A section showing the posterior wall of the pterygopalatine fossa.

The *pterygopalatine fossa* (sphenomaxillary fossa) (figs. 355, 360) is a pyramidal space situated beneath the apex of the orbit at the angle of j- of the inferior orbital and pterygomaxillary fissures. It is bounded by the under surface of the body of the sphenoidal bone and by the process of the palatine bone; in front, by the upper part of the infrat- surface of the maxilla; behind, by the base of the pterygoid process a- lower part of the anterior surface of the great wing of the sphenoid- medially, by the vertical part of the palatine bone with its orbital and sph- processes. The fossa contains the maxillary nerve, the sphenopalatine gan- and the terminal part of the internal maxillary artery. Five foramin- into it. Of these, three are on the posterior wall, viz.: the foramen rotu- the pterygoid canal, and the pharyngeal canal, in this order downwar- medialwards; on the medial wall is the sphenopalatine foramen; b- the superior orifice of the pterygopalatine canal.

Norma Occipitalis

When viewed from behind, the cranium presents a more or less c- outline. In the upper portion of the middle line is the posterior part sagittal suture connecting the parietal bones; extending downward- lateralwards from the posterior end of this suture is the deeply serrated lam- suture joining the occipital and parietal bones, and continuous below w- parietomastoid and occipitomastoid sutures; the lambdoid suture fre- contains one or more sutural bones (fig. 325). Near the middle of the o- squama is the external occipital protuberance or inion, and, extending l- wards from it, the superior nuchal lines, and above these the faintly m- highest nuchal lines. The surface of the occipital bone above the inio- highest nuchal lines is named the planum occipitale, and is covered b- Occipitalis muscle; the surface below is termed the planum nuchale,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

naticofacial nerve. On the upper part of the body of the mandible is
ian ridge, indicating the position of the symphysis or junction of the two
of which the bone is composed at an early period of life; this ridge
s below to enclose the mental protuberance, the lateral angles of which
med the mental tubercles. Below the incisor teeth is the incisive fossa;
h the second premolar tooth is the mental foramen which transmits the
l nerve and vessels. The oblique line ascends from the mental tubercle
continuous behind with the anterior border of the ramus. The posterior
of the ramus runs downwards and forwards from the condyle to the
which is more or less everted.

58.—A horizontal section through the nasal and orbital cavities. Superior aspect.

e orbits (figs. 356 to 360) are two pear-shaped cavities, situated at
nction of the cranium with the face, their bases being directed forwards
teralwards, and their apices backwards and medialwards, so that the
xes of the cavities, if continued backwards, would meet over the body
sphenoidal bone. Each orbit has a roof, a floor, a medial and a lateral
a base, and an apex.

e *roof* of the orbit is thin, triangular, and concave, and is directed down-
and slightly forwards. It separates the orbital from the cranial cavity,
s anteromedial part is double owing to the extension into it of the frontal
ns, and sometimes also the ethmoidal air-sinuses. It is formed in front
e orbital plate of the frontal bone, and behind by the small wing of the
oidal bone, which is pierced by the optic foramen. It presents, just within
e of the orbit and about midway between the supra-orbital notch and
ntolacrimal suture, a small depression or spine, the fovea vel spina
aris, for the attachment of the fibrocartilaginous pulley of the Obliquus
superior; on its anterolateral part is the lacrimal fossa for the lacrimal
; posteriorly is the suture between the frontal bone and the small wing
sphenoidal bone.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The *floor* of the orbit (fig. 358) looks upwards and lateralwards, a shortest of the four walls; it separates the orbital cavity from the air-sinus. Triangular in shape, it is formed chiefly by the orbital surf maxilla; in front and laterally, by the orbital process of the zygoma behind and medially, to a small extent, by the orbital process of the bone. At its medial angle is the upper opening of the nasolacrim immediately to the lateral side of which is a small depression on th surface of the maxilla for the origin of the Obliquus oculi inferior. lateral part of the floor is the suture between the maxilla and the z bone, and at its posterior part the suture between the maxilla and th process of the palatine bone. Running forwards near the middle of is the infra-orbital groove, ending anteriorly in the infra-orbital c transmitting the infra-orbital nerve and vessels.

FIG. 359.—The medial wall of the left orbit.

The *medial wall* of the orbit (fig. 359) is nearly vertical. It is ve and separates the orbital cavity from the ethmoidal air-sinuses, and fr anterior part of the sphenoidal air-sinus. It is formed from before ba by the frontal process of the maxilla behind the anterior lacrimal cr lacrimal bone and the small part of the frontal bone directly above lamina papyracea of the ethmoidal bone, and a small portion of the the sphenoidal bone in front of the optic foramen; sometimes the sp concha forms a small part of this wall (p. 205). It exhibits three vertical viz. the lacrimomaxillary, lacrimo-ethmoidal, and spheno-ethmoidal. I is seen the lacrimal fossa, which lodges the lacrimal sac, and behind th is the posterior lacrimal crest, from which the lacrimal part of the Orb oculi arises. At the junction of the medial wall and the roof are the maxillary, frontolacrimal, fronto-ethmoidal, and frontosphenoidal sutur the fronto-ethmoidal suture are the anterior and posterior ethmoidal fo for the transmission of the corresponding ethmoidal nerves and vessels.

The *lateral wall* of the orbit (fig. 360), directed medialwards and fo is formed by the orbital surface of the zygomatic bone and the orbital

THE INTERIOR OF THE SKULL

In order to study the interior of the skull, the skull-cap should be by a saw-cut carried round the cranium about the level of the frontal and the upper limits of the squamosal sutures, cutting the occipital bo above its external protuberance.

The Internal Surface of the Skull-cap

On the concave internal surface of the skull-cap are depressions convolutions of the cerebrum, and numerous furrows for the branch meningeal vessels. In the middle line is the sagittal sulcus, narrow and broad behind; it lodges the superior sagittal sinus, and its marg attachment to the falx cerebri. On either side of the sulcus are sever sions for the arachnoideal granulations, and, at its posterior part, the of the parietal foramina when these are present. It is crossed in fro coronal suture, and behind by the lambdoid suture, whilst the sagitt is in the middle line between the parietal bones.

The Internal Surface of the Base of the Skull (Basis Cranii I (figs. 361, 362)

The internal surface of the base of the skull, or floor of the crani is divided into anterior, middle, and posterior cranial fossæ.

The **anterior fossa.**—The floor of this fossa is formed by the orbi of the frontal bone, the lamina cribrosa of the ethmoidal bone, and wings and the anterior part of the body of the sphenoidal bone; it behind by the posterior borders of the small wings of the sphenoidal by the anterior margin of the sulcus chiasmatis. It is traversed by th ethmoidal, spheno-ethmoidal and sphenofrontal sutures. Its lateral form the roofs of the orbital cavities and support the frontal lobes of brum; they are convex and marked by depressions for the brain conv and by grooves for branches of the meningeal vessels. The central of the floor corresponds with the roof of the nasal cavity, and is depressed on either side of the crista galli. It presents, in the med from before backwards, the commencement of the frontal crest for th ment of the falx cerebri; the foramen cæcum which frequently opens nasal cavity and transmits a small vein from that cavity to the superior sinus; the crista galli, the free margin of which affords attachment anterior end of the falx cerebri. On either side of the crista galli is the groove formed by the lamina cribrosa of the ethmoidal bone, which the olfactory bulb and is perforated by foramina for the transmissio olfactory nerves; at the front part of the lamina cribrosa is the fora the anterior ethmoidal nerve. Lateral to the olfactory groove are the openings of the anterior and posterior ethmoidal foramina; the situated about the middle of the lateral margin of the olfactory groove, t the anterior ethmoidal nerve and vessels; the nerve runs in a groo the lateral edge of the lamina cribrosa to the foramen above mention posterior ethmoidal foramen opens at the posterior part of this marg cover of a projecting lamina of the sphenoidal bone, and transmits the ethmoidal nerve and vessels. The anterior margin of the sulcus ch runs lateralwards to the upper margins of the optic foramina.

The **middle fossa.**—This fossa is deeper than the anterior, and is the middle, and wide at the sides of the skull. It is bounded in front posterior margins of the small wings of the sphenoidal bone, the anterior processes, and the ridge forming the anterior margin of the sulcus chi behind, by the dorsum sellæ of the sphenoidal bone and the superior (superior margins) of the petrous portions of the temporal bones; late

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

emporal squamæ, the sphenoidal angles of the parietal bones, and the wings of the sphenoidal bone. It is traversed by the squamosal, spheno-al, sphenosquamosal, and sphenopetrosal sutures.

he middle part of the fossa presents, in front, the sulcus chiasmatis and culum sellæ; the sulcus ends on either side at the optic foramen, which mits the optic nerve and ophthalmic artery to the orbital cavity. The or clinoid process is directed backwards and medialwards behind the foramen and gives attachment to the anterior end of the free border e tentorium cerebelli. Behind the tuberculum sellæ is the sella turcica, eepest part of which lodges the hypophysis and is named the fossa hypo-os. At the lateral angles of the anterior wall of the sella turcica are iddle clinoid processes. The sella turcica is bounded posteriorly by the m sellæ, the upper angles of which are surmounted by the posterior d processes; these afford attachment to the lateral borders of the tentorium lli, and a little below each process the side of the dorsum sellæ is notched e passage of the abducent nerve. Lateral to the sella turcica is the d sulcus, which begins behind at the foramen lacerum, and ends on the l side of the anterior clinoid process, where it is sometimes converted into men (caroticoclinoid) by the union of the anterior and middle clinoid pro-; the posterior part of the sulcus is bounded anterolaterally by the The carotid sulcus lodges the cavernous sinus, the internal carotid and the plexus of sympathetic nerves surrounding the latter.

e lateral parts of the middle fossa are deep, and support the temporal of the brain. They are marked by depressions for the brain convolutions, re traversed by furrows for the anterior and posterior branches of the e meningeal vessels. These furrows begin by the bifurcation of a groove commences at the foramen spinosum and runs for about 2 cm. forwards ateralwards on the temporal squama; the anterior furrow is directed rds and upwards to the sphenoidal angle of the parietal bone, where it is times converted into a bony canal; the posterior furrow arches backwards s the upper part of the temporal squama and passes on to the parietal near the middle of its lower border. In the anterior part of the fossa e superior orbital fissure, bounded above by the small wing, below by the wing and medially by the body, of the sphenoidal bone; it is usually ted laterally by the orbital plate of the frontal bone. It transmits to the l cavity the oculomotor, trochlear, and abducent nerves, the three ches of the ophthalmic nerve, and some filaments from the cavernous s of the sympathetic; and from the orbital cavity the recurrent meningeal h of the lacrimal artery, and the ophthalmic veins. Behind the medial f the superior orbital fissure is the foramen rotundum, for the exit of the lary nerve. Posterior and lateral to the foramen rotundum is the foramen which transmits the mandibular nerve, the accessory meningeal artery, e lesser superficial petrosal nerve.* Medial to the foramen ovale is the men Vesalii which varies in size, and is often absent; when present, it opens at the lateral side of the scaphoid fossa, and transmits a small vein. Lateral e foramen ovale is the foramen spinosum, for the passage of the nervus sus and the middle meningeal artery. Medial and posterior to the foramen is the foramen lacerum; in the recent state the lower part of this foramen d by a fibrocartilaginous plate, on the upper surface of which rests the al carotid artery surrounded by a plexus of sympathetic nerves; the of the pterygoid canal, and a meningeal branch from the ascending ngeal artery, pierce the fibrocartilaginous plate. On the anterior surface e petrous portion of the temporal bone is the eminentia arcuata caused e upward projection of the superior semicircular canal; in front of this, epressed area forming the roof of the tympanic cavity, and the groove ng to the hiatus of the facial canal for the transmission of the greater cial petrosal nerve and the petrosal branch of the middle meningeal lateral to this groove, the smaller groove for the passage of the lesser cial petrosal nerve; and, near the apex of the bone, the depression for milunar ganglion, and the internal orifice of the carotid canal.

e posterior fossa.—The posterior fossa, the largest and deepest, is formed e dorsum sellæ of the sphenoidal bone, the basilar and lateral parts of the

and the vaginal process of the medial pterygoid lamina; below, by the rior border of the horizontal part of the palatine bone; laterally, by edial pterygoid lamina.

FIG. 366.—The lateral wall of the right nasal cavity, with parts of the middle and inferior nasal conchæ removed.

THE DIFFERENCES IN THE SKULL DUE TO AGE

t birth the skull is large in proportion to the other parts of the skeleton, but se is short and narrow in proportion to the vault; the facial portion is small quals only about one-eighth of the bulk of the cranium as compared with lf in the adult. The frontal and parietal tuberosities or eminences are promi- and when the skull is viewed from above it presents a pentagonal outline its greatest width at the parietal tuberosities (fig. 367); on the other hand, abella, superciliary arches, and mastoid processes are not developed. Ossi- on of the skull bones is not completed, and many of them—e.g. the occipital, rals, sphenoidal, frontal, and mandible—consist of more than one piece. ified membranous intervals, termed fonticuli (fontanelles), are seen at the of the parietal bones; these fonticuli are six in number; two, the frontal cipital, are situated in the middle line, and two, the sphenoidal and mastoid, er side.

e *frontal or anterior fonticulus* (fig. 367) is the largest, and is placed at the on of the sagittal, coronal, and frontal sutures; it is lozenge-shaped, and res about 4 cm. in its anteroposterior and 2·5 cm. in its transverse diameter. *ccipital or posterior fonticulus* (fig. 367) is triangular in form and is situated

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

at the junction of the sagittal and lambdoid sutures. The *sphenoidal* and *fonticuli* (fig. 368) are small, irregular in shape, and correspond respectively the sphenoidal and mastoid angles of the parietal bones. An additional is sometimes seen in the suture at the region of the

Fig. 367.—The skull at birth, showing the frontal and occipital fonticuli. Superior aspect.

The fonticuli are usually the growth and extension of which surround them, but they are the sites of separate of ossification which deve sutural bones. The occi sphenoidal fonticuli are o within two or three mont birth; the mastoid fonti usually closed about the en first year, and the frontal fo about the middle of the seco

The smallness of the face is mainly accounted for by mentary condition of the and maxillæ, the non-erup the teeth, and the small size maxillary air-sinuses and cavities. At birth the nasal lie almost entirely betwe orbits, and the lower borde anterior nasal aperture is little below the level of the floor. With the eruption deciduous teeth there is an ment of the face and jaws, a changes are still more mark the second dentition.

The skull grows rapidly from birth to the seventh year; at the latter lamina cribrosa of the ethmoidal bone, the foramen magnum, and the parts of the temporal bones have reached their full size, and the orbital cav

Fig. 368.—The skull at birth, showing the sphenoidal and mastoid fonti Left lateral aspect.

only a little smaller than those of the adult. Growth is slow from the year until the approach of puberty, when a second period of increased

rs: this results in an enlargement in all directions, but especially in the frontal facial regions, where it is associated with the development of the air-sinuses. bliteration of the sutures of the vault of the skull takes place as age nces. It may commence between the ages of thirty and forty on the inner ce, and about ten years later on the outer surface of the skull, but the times hich the sutures are closed are subject to great variations. Obliteration usually s first in the lower part of the coronal suture, next in the posterior part of the al suture, and then in the lambdoid suture.

In old age the skull generally becomes thinner and lighter, but in a small portion of cases it increases in thickness and weight. The most striking feature e senile skull is the diminution in the size of the mandible and maxillæ consequent on the loss of the teeth and the absorption of the alveolar processes. This sociated with a marked reduction in the vertical measurement of the face with an alteration in the angles of the mandible.

The Sex Differences in the Skull

ntil the age of puberty there is little difference between the skull of the female hat of the male. The skull of an adult female is as a rule lighter and smaller, s capacity is about 10 per cent. less, than that of the male. Its walls are r and its muscular ridges less marked; the glabella, superciliary arches, and id processes are less prominent, and the corresponding air-sinuses are small dimentary. The upper margin of the orbit is sharp, the forehead vertical, rontal and parietal tuberosities prominent, and the vault somewhat flattened. ontour of the face is rounder, the facial bones are smoother, and the mandible maxillæ and their contained teeth smaller. Speaking generally, more of infantile characteristics are retained in the skull of the adult female than in of the adult male. A well-marked male or female skull can easily be recognised ch, but in some skulls the respective characteristics are so indistinct that the rmination of the sex may be difficult or impossible.*

Craniology

kulls vary in size and shape, and the term craniology is applied to the study of these tions.

he *capacity* of the cranial cavity constitutes a good index of the size of the brain h it contained, and is most conveniently arrived at by filling the cavity with shot and uring the contents in a graduated vessel. Skulls may be classified according to their acities as follows:

Microcephalic, with a capacity of less than 1350 c.cm.—e.g. those of native ralians and Andaman Islanders.

Mesocephalic, with a capacity of from 1350 c.cm. to 1450 c.cm.—e.g. those of n negroes and Chinese.

Megacephalic, with a capacity of over 1450 c.cm.—e.g. those of Europeans, nese and Eskimos.

n comparing the shape of one skull with that of another it is necessary to adopt some ite position in which the skulls should be placed during the process of examination. should be so placed that a line carried through the lower margin of the orbit and r margin of the opening of the external acoustic meatus is in the horizontal plane. normæ of one skull can then be compared with those of another, and the differences ontour and surface-form noted. Further, it is necessary that the various linear asurements used to determine the shape of the skull should be made between definite easily localised points on its surface. The principal points may be divided into two ps: (1) those in the median plane, and (2) those on either side of it (fig. 369).

The **points in the median plane** are the:

Pogonion. The most prominent point of the chin.

Alveolar point or *prosthion*. The central point of the anterior margin of the upper olar arch.

Rhinthion. The tip of the anterior nasal spine.

Rhinnasal point. The middle of the lower border of the anterior nasal aperture, at the of the anterior nasal spine.

Nasion. The most prominent point of the internasal suture.

Bregma. The central point of the frontonasal suture.

Glabella. The point in the middle line at the level of the superciliary arches.

* Some additional differences between the male and female skull are given by Professor F. G. ...as and Mrs. Lucas Keene, *Journal of Anatomy*, vol. liv, 1919.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Ophryon. The point in the middle line of the forehead at the level where the lines most nearly approach each other.

Bregma. The meeting point of the coronal and sagittal sutures.

Obelion. A point in the sagittal suture on a level with the parietal foramina.

Lambda. The point of junction of the sagittal and lambdoid sutures.

Occipital point. The point in the middle line of the occipital bone farthest from the glabella.

Inion. The external occipital protuberance.

Opisthion. The mid-point of the posterior margin of the foramen magnum.

Basion. The mid-point of the anterior margin of the foramen magnum.

FIG. 369.—An outline of the left side of the skull.

The **points on either side of the median plane** are the:

Gonion. The outer margin of the angle of the mandible.

Jugal point. The angle between the temporal border of the zygomatic bone and the upper border of the zygomatic arch.

Dacryon. The point of union of the anterosuperior angle of the lacrimal with the frontal bone and the frontal process of the maxilla.

Pterion. The point where the great wing of the sphenoidal bone joins the squamous angle of the parietal.

Stephanion. The point where the temporal line intersects the coronal suture.

Auricular point. The centre of the orifice of the external acoustic meatus.

Supra-auricular point. A point on the posterior root of the zygomatic arch in the middle of the orifice of the external acoustic meatus.

Asterion. The point of meeting of the lambdoid, masto-occipital, and masto-parietal sutures.

The *horizontal circumference* of the cranium is measured in a plane passing through the glabella in front, and the occipital point behind; it averages about 50 cm. in the female and 52·5 cm. in the male.

The *occipitofrontal or longitudinal arc* is measured from the nasion over the vertex line of the vertex to the opisthion, while the *basinasal length* is the distance between the basion and the nasion. These two measurements, plus the anteroposterior diameter of the foramen magnum, represent the *vertical circumference* of the cranium.

The *length* is measured from the glabella to the occipital point, while the *breadth* or greatest transverse diameter is usually found a little above and behind the opening of the external acoustic meatus. The proportion of breadth to length $\frac{\text{breadth}}{\text{length}}$ is termed the *cephalic index* or *index of breadth.*

The *height* is measured from the basion to the bregma, and the proportion of height to length $\frac{\text{height} \times 100}{\text{length}}$ constitutes the *vertical or height index.*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

studying the face the principal points to be noticed are the proportion of its length breadth, the shape of the orbits and of the anterior nasal aperture, and the degree of tion of the jaws.

e *length of the face* is measured from the nasion to the lower margin of the man- or, if the mandible be wanting, to the alveolar point; its *width* is the distance en the zygomatic arches. By comparing the length with the width of the face, may be divided into two groups; *dolichofacial* (long-faced) and *brachyfacial* -faced).

e *orbital index* signifies the proportion which the orbital height bears to the orbital thus:

$$\frac{\text{orbital height} \times 100}{\text{orbital width}}$$

e *nasal index* expresses the proportion which the width of the anterior nasal ure bears to the height of the nose, the latter being measured from the nasion to the sal point, thus:

$$\frac{\text{nasal width} \times 100}{\text{nasal height}}$$

e degree of projection of the jaws is determined by the *gnathic or alveolar index*, represents the proportion between the basi-alveolar and basinasal lengths, thus:

$$\frac{\text{basi-alveolar length} \times 100}{\text{basinasal length}}$$

e *dental index* is arrived at by comparing the *dental length* (i.e. the distance en the anterior surface of the first premolar and the posterior surface of the third tooth of the maxilla) with the basinasal length, thus:

$$\frac{\text{dental length} \times 100}{\text{basinasal length}}$$

e following table, modified from that given by Duckworth,* illustrates how some of indices may be utilised in the classification of skulls:

Index.	Classification.	Nomenclature.	Examples.
Cephalic .	Below 75 . . .	Dolichocephalic .	Kaffirs and Native Australians
	Between 75 and 80 .	Mesaticephalic .	Europeans and Chinese
	Above 80 . . .	Brachycephalic .	Mongolians and Andamans
Orbital .	Below 84 . . .	Microseme . .	Tasmanians and Native Australians
	Between 84 and 89 .	Mesoseme . .	Europeans
	Above 89 . . .	Megaseme . .	Chinese and Polynesians
Nasal . .	Below 48 . . .	Leptorhine . .	Europeans
	Between 48 and 53 .	Mesorhine . .	Japanese and Chinese
	Above 53 . . .	Platyrhine . .	Negroes and Native Australians
Gnathic .	Below 98 . . .	Orthognathous .	Europeans
	Between 98 and 103 .	Mesognathous .	Chinese and Japanese
	Above 103 . . .	Prognathous .	Native Australians

plied Anatomy.—Occasionally a protrusion of the brain or its membranes may take through one of the sutures, owing to non-closure. When the protrusion consists of branes only, and is filled with cerebrospinal fluid, it is called a *meningocele*; when it ts of brain as well as membranes, it is termed an *encephalocele*. These malforma- are usually found in the middle line, and most frequently at the back of the head, trusion taking place between the centres of ossification of the occipital squama 200.) They generally occur through the upper part of the vertical fissure, which last to close, but not uncommonly through the lower part, when the foramen m may be incomplete. More rarely these protrusions are met with in other ions, as in the sagittal, lambdoid, and other sutures, or through abnormal gaps at des or base of the skull.

The chief function of the skull is to protect the brain, and therefore those
the skull which are most exposed to external violence are thicker than those
shielded from injury by overlying muscles. Thus, the skull-cap is thick
whereas the temporal squamæ, being protected by the Temporales muscles
inferior occipital fossæ, being shielded by the muscles at the back of the neck,
fragile. Fracture of the skull is further prevented by its elasticity, its roun
and its construction of a number of secondary elastic arches, each made up
bone. The manner in which vibrations are transmitted through the bones of
also of importance as regards its protective mechanism, at all events as far as
concerned. In the vault, the bones being of a fairly equal thickness and den
tions are transmitted in a uniform manner in all directions, but in the base, ow
varying thickness and density of the bones, this is not so; and therefore in this
there are special buttresses which serve to carry the vibrations in certain defi
tions. At the front of the skull, on either side, is the ridge which separates th
from the middle fossa of the base; and behind, the ridge or buttress which sep
middle from the posterior fossa; and if any violence is applied to the vault, the
would be carried along these buttresses to the sella turcica, where they meet. Th
been termed the 'centre of resistance,' and here there is a special protective m
to guard the brain. The subarachnoid cavity at the base of the brain is dilated
cerebrospinal fluid which fills it acts as a water-cushion to shield the brain fro
In like manner, when violence is applied to the base of the skull, as in falls upo
the vibrations are carried backwards through the occipital crest, and forwards
the basilar part of the occipital and body of the sphenoidal bone to the vau
skull.

Fractures of the skull are best considered as affecting either the vault or
Fractures of the vault generally involve the whole thickness of the bone; but s
the inner table alone is fractured, and portions of it driven inwards. In fractu
skull, and especially in punctured fractures, the inner table is more splintered
minuted than the outer, and this is due to several causes. It is thinner and mo
the force of the violence as it passes inwards becomes broken up and is more d
the time it reaches the inner table; the bone being in the form of an arch bends
and spreads out, and thus presses the particles together on the convex surface of
i.e. the outer table, and forces them asunder on the concave surface or inner ta
lastly, there is nothing firm under the inner table to support it and oppose the forc
tures of the vault may be either simple, or starred and comminuted, and the
may be depressed or elevated. Cases of fracture with elevation of the fractures
are uncommon, and can only be produced by direct wound. In comminuted
a portion of the skull is broken into several pieces, the lines of fracture radiatin
centre where the chief impact of the blow was felt; if the fracture is also dep
fissure circumscribes the radiating lines, enclosing a portion of the skull. If
is circular it is termed a 'pond' fracture, and has probably been caused by a roun
ment, as a life-preserver or hammer; if elliptical in shape it is termed a 'gutter'
and owes its shape to the instrument which has produced it, as a poker. Fractu
outer table alone may occur in the region of the frontal air-sinuses where the t
are completely separated.

Fractures of the base of the skull may be produced by *indirect* or *direct* violen

I. In cases of the former class the violence is applied to the vertex or some p
cranial convexity, as when a person falls from a height on to his head and a fr
the base results. The mechanism of this form of fracture is explained, (*a*) by
of a fissure from the vertex to the base, or (*b*) by compression causing bursting
place at a weak point in the base.

II. Direct violence may be applied to the base of the skull in several differe
by the impact of the vertebral column against the condyles of the occipital bon
on the buttocks or feet; by the condyle of the mandible being driven against th
bular fossa, in blows or falls on the chin; by the thrusting of a pointed in
through the orbit or nose; by gunshot wounds through the mouth; and by a fall
on the back of the head.

In the majority of cases the fracture is compound. The most common place
ture of the base to occur is through the middle fossa, and here the fissure usually
fairly definite course. Starting from the point struck, which is generally some
the neighbourhood of the parietal eminence, it runs downwards through the par
the temporal squama and across the petrous portion, frequently traversing and in
the internal acoustic meatus, to the foramen lacerum. From this it may pass a
body of the sphenoidal bone, through the sella turcica, to the foramen lacerum of
side, and may indeed travel round the whole cranium so as completely to sep
anterior from the posterior part. The course of the fracture explains the sym
which fracture in this region may give rise: thus if the fissure pass across the
acoustic meatus injury to the facial and acoustic nerves may result, with co
facial paralysis and deafness; if the fissure extends through the semicircular can
ness will be complained of, especially on turning the head sideways; or the tub
longation of the arachnoid around the nerves in the meatus may be torn and the
of the escape of the cerebro-spinal fluid should there be a communication bet

CC-0.In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

al ear and the tympanic cavity together with rupture of the tympanic membrane, frequently the case: again, if the fissure pass across the sella turcica, and the mucoeum covering the under surface of the body of the sphenoidal bone is torn, blood nd its way into the pharynx and be swallowed, and after a time vomiting of blood sult. Fractures of the anterior fossa, involving the bones forming the roof of the and nasal cavity, are generally the result of blows on the forehead; but fracture lamina cribrosa of the ethmoid may be a complication of fracture of the nasal bone. the fracture implicates the roof of the orbit, the blood finds its way into this cavity, avelling forwards, appears as a subconjunctival ecchymosis. If the roof of the nasal be fractured, the blood escapes from the nose. In rare cases there may be also of cerebrospinal fluid from the nose should the dura mater and arachnoid have orn. In fractures of the posterior fossa, extravasation of blood may appear at the f the neck, beneath the muscles attached to the superior nuchal line of the occipital

formities of the skull.—General enlargement of the skull, producing characteristic nities of various types, occurs in certain rare diseases such as ostitis deformans, egaly, and leontiasis ossea; it also is present in the much commoner disorders, rickets rdrocephalus. In rickety cases the skull becomes enlarged from the formation of cal outgrowths of soft tissue on the outer side of the skull. These deposits are very blood-vessels, and occur between the ridges of the cranial bones and their centres fication, and are symmetrically arranged—often about the anterior fontanelle; s *nodes*, which are local thickenings of the diplöe or of the outer table are often ted with rickets, especially when congenital syphilis coexists. The anterior fonitself, instead of closing about the middle of the second year, remains patent until rd or even the sixth year. The general shape of the skull alters. The forehead is nd square, with prominent frontal eminences, and the head tends to be cubical or haped; the enlargement of the head in rickets appears to be greater than it really ause the development of the facial bones is retarded. The base of the nose may r sunken, from retarded development of the basis cranii. In congenital hydrolus, or enlargement of the head due to the presence of excess of fluid in the ventricles e brain, the cranium becomes globular, and its bones are thin and often widely ated.

e bones of the face are sometimes fractured as the result of direct violence. Those commonly broken are the nasal bones and the mandible; the latter is by far the frequently fractured of all the facial bones. Fracture of the *nasal bone* is for the part transverse, and takes place about 1·25 cm. from the free margin. The broken n may be displaced backwards or more generally to one side by the force which ced the lesion. The *zygomatic bone* is probably never broken alone—that is to say, ut fracture of some of the other bones of the face. The *zygomatic arch* is occasionfractured, and when this occurs as a result of direct violence the fragments may be ced inwards. Fractures of the *maxilla* may vary much in degree, from the chipping a portion of the alveolar arch to an extensive comminution of the whole bone from violence, as the kick of a horse. The most common situation for a fracture of the dle is in the neighbourhood of the canine tooth, as at this spot the bone is weakened e deep socket for the root of this tooth; it is next most frequently fractured at the ; then at the symphysis; and finally the neck of the condyle or the coronoid process e broken. Occasionally a double fracture may occur, one in either half of the bone. actures are usually compound, from laceration of the mucous membrane covering ms. Displacement readily occurs and is difficult to rectify; it results in inequality e line of the teeth and is commonly due to the muscles attached in the region of the ysis dragging this portion downwards.

the operation of excision of the maxilla, the central incisor tooth having been cted the incision is begun just below the medial canthus of the eye and passes along de of the nose round the ala and down the middle line of the upper lip into the h. A second incision is made from the commencement of the first along the lower er of the orbit as far as the prominence of the zygomatic bone. The flap thus formed ected, so as to expose the bone. The periosteum attached along the lower margin of rbit is now to be incised, and the periosteum covering the floor of the orbit is raised the bone, for in all cases it is essential that this fibrous layer should not be removed. outh is now widely opened with a gag, and the mucous membrane covering the hard e incised down to the bone in the middle line, and the soft palate separated from the The surgeon having first separated the ala of the nose from its bony attachment. eds to divide the connexions of the maxilla with the other bones of the face. They the junction with the zygomatic bone, the line of section being carried into the or orbital fissure; (2) the frontal process of the maxilla; a small portion of its upper ity, connected with the nasal bone in front, the lacrimal bone behind, and the bone above, being left; (3) the connexion with the opposite maxilla and with the e, are broken through. The bone is now firmly grasped and the remaining attachs of the orbital plate with the ethmoid, and of the back of the bone with the palatine roken through. Occasionally the orbital plate can be saved, and this should always me if possible, as it prevents lowering of the eyeball and consequent double vision. rizontal saw-cut should then be made just below the infra-orbital foramen.

THE EXTREMITIES

The extremities or limbs are four in number: a *superior pair*, mainly to prehension; and an *inferior pair*, intended for support motion. Both pairs are constructed after a common type, but certain differences are observed between them.

The bones by which the upper and lower limbs are attached to constitute respectively the shoulder- and pelvic girdles. The *shoul* or *girdle of the superior extremities* is formed by the scapulæ and clavi is imperfect in front and behind. In front, however, it is complete upper end of the sternum, with which the medial ends of the clavicles a Behind, it is widely imperfect, the scapulæ being connected to the muscles only. The *pelvic girdle* or *girdle of the inferior extremities* is by the hip-bones which articulate with each other in front at the sy pubis. It is imperfect behind, but the gap is filled by the upper par sacrum. The pelvic girdle, with the sacrum, is a complete ring, mas comparatively rigid, in marked contrast to the lightness and mobility shoulder-girdle.

THE BONES OF THE SUPERIOR EXTREMITY

The Scapula

The **scapula** or shoulder-blade is a flat, triangular bone, with two three processes, three borders, and three angles. On the lateral a shallow concavity, the *glenoid cavity*, for articulation with the head humerus.

The *costal surface* (fig. 370) presents a broad cavity, the *subscapul* the medial two-thirds of which are marked by several oblique ridges lateralwards and upwards. The ridges give attachment to the te intersections, and the surfaces between them to the fleshy fibres, Subscapularis; the lateral one-third of the fossa is smooth and in cont this muscle. The fossa is separated from the vertebral border by triangular areas at the medial and inferior angles of the bone, and in the between the angles by a narrow ridge; these triangular areas and the inte narrow ridge afford attachment to the Serratus anterior. At the up of the fossa the bone is bent on itself along a line corresponding w attached margin of the spine.

The *dorsal surface* (fig. 371) is arched from above downwards, and divided into two fossæ by a projecting plate of bone, the *spine*; the above the spine is called the supraspinatous fossa, and that below it th spinatous fossa. The *supraspinatous fossa* is concave and smooth; its two-thirds give origin to the Supraspinatus. The *infraspinatous fossa* is larger than the preceding; towards its vertebral margin a shallow co is present at its upper part; the central part is convex, while that n axillary border is deeply grooved. From the medial two-thirds of th the Infraspinatus takes origin; the lateral one-third is in contact wi muscle. From the lower part of the glenoid cavity an elevated ridge runs wards and backwards and reaches the vertebral border, about 2·5 cm. the inferior angle; it gives attachment to a fibrous septum which separa Infraspinatus from the Teres major and Teres minor. The upper p the surface between the ridge and the axillary border is narrow; it gives to the Teres minor, and is crossed by a shallow groove for the passage scapular circumflex vessels. The lower part of the surface is sou triangular, and gives origin to the Teres major. The two parts are sep by an oblique line which runs downwards and backwards from the a border; a fibrous septum is attached to this oblique line, and separa Teres major from the Teres minor. The upper portion of the Lat dorsi glides over the Teres major, and frequently derives a few fibres of from the inferior angle of the bone.

ructure.—The head, processes, and thickened parts of the scapula contain y substance; the rest consists of a thin layer of compact bone. The central f the supraspinatous fossa and the greater part of the infraspinatous fossa are occasionally the bone is wanting in these situations, the gaps being filled rous tissue.

sification (fig. 373).—The scapula is ossified from seven or more centres: r the body, two for the coracoid process, two for the acromion, one for the ral border, and one for the inferior angle.

e centre for the body appears in the eighth week of fœtal life, and spreads m an irregular quadrilateral plate of bone, immediately behind the glenoid . This plate forms the chief part of the bone, and the spine grows up from rsal surface about the third month. At birth, the glenoid cavity, coracoid s, acromion, vertebral border, and inferior angle are cartilaginous. In the ear of life, ossification begins in the middle of the coracoid process, and this s joins the rest of the bone about the fifteenth year. Between the fourteenth wentieth years, ossification of the remaining parts usually takes place in the ing order; first, in the root of the coracoid process; second, near the of the acromion; third, in the inferior angle and contiguous part of rtebral border; fourth, near the extremity of the acromion; fifth, in the ral border. The base of the acromion is formed by an extension from ne; the rest of the acromion is ossified from two centres which unite, and oin the extension from the spine. The upper one-third of the glenoid is ossified from a subcoracoid centre, which appears between the tenth eventh, and joins between the sixteenth and the eighteenth, years. Further, physial plate appears for the lower part of the glenoid cavity, while the tip of racoid process frequently presents a separate centre. These various epiphyses ined to the bone by the twenty-fifth year.

plied Anatomy.—Fractures of the body of the scapula are rare, owing to the ity of the bone, the thick layers of muscles by which it is encased, and the elasticity ribs on which it rests. The most frequent course of a fracture is from the scapular to the infraglenoid tuberosity, and it derives its principal interest from its simula- f a subglenoid dislocation of the humerus. The diagnosis can be made by noting teration in the position of the coracoid process. The acromion is more frequently n than any other part of the bone, and fibrous union is very liable to follow. Failure y union between the acromion and spine sometimes occurs and may simulate a re; and the junction of these two parts may be then effected by fibrous tissue, or imperfect articulation.

e presence of 'winged scapulæ' (scapulæ alatæ) described in thin persons of feeble lar development in whom the lower angles of the scapulæ project unduly, is due to abnormal roundness of the thoracic wall, and partly to weakness and flaccidity Latissimus dorsi and Serratus anterior. The shoulders are held low in these subjects, e clavicles slope downwards and forwards, carrying with them the scapulæ, which the posterior wall of the chest and so tend to project from it.

The Clavicle (Clavicula)

e clavicle or collar-bone (figs. 374, 375) articulates medially with the brium sterni, and laterally with the acromion of the scapula.* It is a bone, and is placed nearly horizontally at the upper and anterior part of horax. It is bent somewhat like the italic letter *f*, presenting a double ature, with a convexity forwards at the sternal end and a concavity forwards e acromial end. Its lateral one-third is flattened, whilst its medial two- s are cylindrical or prismoid in form.

e lateral one-third of the clavicle has two surfaces, an upper and a lower, two borders, an anterior and a posterior. The *upper surface* is flat and d; it affords attachment to the Deltoideus in front, and the Trapezius d; between these a small portion of the surface is subcutaneous. The

e clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to . It is accordingly absent in those animals whose fore-limbs are used only for progression, present for the most part in animals whose anterior extremities are clawed and used for sion, though in some of them—as, for instance, in a large number of the carnivora—a rudimentary bone suspended among the muscles, and not articulating with either the a or the sternum.

lower surface is flat; at its posterior border, near the junction with the two-thirds of the bone, is a rough eminence, the *coracoid tuberosity* tubercle); this overlies the coracoid process of the scapula, and gives ment to the conoid ligament. From this tuberosity, the *oblique or ridge* runs forwards and lateralwards, and affords attachment to the ligament. The *anterior border* is concave, thin, and rough, and gives a portion of the Deltoideus; at its medial part there is frequently a the *deltoid tubercle*. The *posterior border*, convex, rough, and thicker anterior, gives insertion to a part of the Trapezius.

The **medial two-thirds** of the clavicle constitute the prismoid portion bone, which is marked by three borders, separating three surfaces. The *border* is continuous with the anterior border of the flat portion. Its lat is smooth, and corresponds to the interval between the attachment

Fig. 374.—The left clavicle. Superior aspect.

Fig. 375.—The left clavicle. Inferior aspect.

Pectoralis major and Deltoideus; its medial part forms the lower bo of an elliptical surface for the attachment of the clavicular portion Pectoralis major. The *superior border* is continuous with the posterior of the flat portion, and separates the anterior from the posterior surface. S and rounded laterally, it becomes rough towards the medial one-third attachment of the Sternocleidomastoideus, and ends at the upper a the sternal extremity. The *subclavian or posterior border* separates the p from the inferior surface, and extends from the coracoid tuberosity costal tuberosity; it forms the posterior boundary of the groove for th clavius, and gives attachment to a layer of cervical fascia which co the Omohyoideus. The *anterior surface* is between the superior and a borders. Its lateral part looks upwards, and is continuous with the s surface of the flattened portion; it is smooth, convex, and nearly subcut being covered only by the Platysma. Its medial part is divided by a subcutaneous region into two areas; a lower, elliptical in form, and di forwards, for the attachment of the Pectoralis major; and an upper, attachment of the clavicular part of the Sternocleidomastoideus. The p *or cervical surface* is smooth, and looks backwards towards the root of th It is limited, above, by the superior border; below, by the subclavian

ally, by the margin of the sternal extremity; and laterally, by the coracoid rosity. It is in relation with the transverse scapular vessels, and, at the tion of the curves of the bone, with the brachial plexus of nerves and ubclavian vessels. Near the sternal end, this surface gives attachment to of the Sternohyoideus; and near the middle of this surface is a foramen he transmission of a nutrient artery which runs lateralwards into the A second nutrient artery may enter this, or the inferior, surface. The or or *subclavian surface* is between the anterior and subclavian borders. narrow medially, but increases in width laterally, and is continuous with ower surface of the lateral one-third. On its medial part is a rough area, stal *tuberosity* (rhomboid impression), rather more than 2 cm. in length, e attachment of the costoclavicular ligament. The rest of this surface is ed, and gives insertion to the Subclavius muscle; the coracoclavicular splits to enclose the muscle and is attached to the margins of the groove. he sternal end of the clavicle is triangular in form, and is directed medial- s, and a little downwards and forwards. On it is an articular facet which ncave from before backwards, and convex from above downwards; it lates with the articular disc of the sternoclavicular joint. This facet is ued on to the anterior and inferior sufaces of the bone as a small semi-oval for articulation with the cartilage of the first rib. The circumference of icular surface is rough for the attachment of ligaments; the upper angle narrow rough area below it give attachment to the articular disc.

e acromial end of the clavicle presents a small, flattened, oval surface ed slightly downwards, for articulation with the acromion of the scapula. upper margin of the facet is rough for the attachment of the acromio- ular ligament.

n the female, the clavicle is shorter,* thinner, less curved, and smoother in the male. In the female the acromial end is a little below the level of ternal end; in the male it is on a level with, or slightly higher than, the al end. In persons who perform hard manual labour the clavicle is er and more curved, and its ridges for muscular attachment are better ed.

ructure.—The clavicle consists of spongy substance, enveloped by a layer mpact bone which is much thicker in the intermediate part than at the ends e bone.

ssification.—The clavicle begins to ossify before any other bone in the body, s ossified from three centres. The body of the bone is ossified from two primary es, † a medial and a lateral, which appear between the fifth and sixth weeks of life, and fuse about the forty-fifth day; a secondary centre for the sternal ppears about the eighteenth or twentieth year, and unites with the body bone about the twenty-fifth year.

14 mm. embryo the future clavicle is represented by a band of mesoderm which s from the acromion of the scapula to the tip of the first rib, and is continuous with ment of the sternum. In this band a medial and a lateral mass of 'precartilage' eloped, and in the adjacent ends of these masses the two centres for the body of one appear and soon fuse with each other. The sternal and acromial ends of the inous masses are converted into cartilage and into this the ossification of the of the bone extends.

plied Anatomy.—The clavicle is very frequently fractured, since it is much exposed ence, and is the only bony connexion between the upper limb and the trunk, acting buttress to keep the point of the shoulder away from the thorax. It is, moreover, , and is very superficial. The most common cause is indirect violence, as the of force applied to the hand or shoulder, and the bone then gives way at the junction lateral with its intermediate third, that is to say, at the junction of the two curves, is its weakest part. The fracture is generally oblique, and the displacement of the fragment is downwards, forwards, and medialwards. The deformity is mainly due weight of the arm acting upon the fragment when the buttress-like action of the gone, assisted by the muscles which pass from the thorax to the upper extremity.

G. Parsons (*Journal of Anatomy and Physiology*, vol. li.) gives the following as the average of the clavicle in the male and female: male, left, 154 mm., right, 152 mm.; female, 3 mm., right, 138 mm.

ll, *American Journal of Anatomy*, vol. v., 1906; Fawcett, *Journal of Anatomy and ology*, vol. xlvii.; Hanson, *Anatomical Record*, vol. xix. (number 6), 1920.

The medial fragment, as a rule, is little displaced. The main vessels of the
and the great nerve-cords of the brachial plexus lie beneath the bone on the
are liable to be wounded, especially in fracture from direct violence, when the
blow drives the broken ends inwards. Fortunately the Subclavius intervenes
these structures and the clavicle, and often protects them from injury.

The clavicle is occasionally the seat of sarcomatous tumours, rendering the
of excision of the entire bone necessary. This is an operation of considerable
and danger. It is best performed by exposing the bone freely, disarticulating
acromial end, and turning it forwards. The removal of the lateral part is comp
easy, but resection of the medial part is fraught with difficulty, the main da
the risk of wounding the great veins which are in relation with its deep surface.

Great deformity of the clavicle may be met with in rickets, the natural cur
the bone being exaggerated until it takes an S shape, and 'green-stick' frac
uncommonly seen associated therewith.

The Humerus

The **humerus** (figs. 377, 378), the longest and largest bone of th
limb, is divisible into a body or shaft, and two ends.

The **upper end** consists of the *head* and the *greater* and *lesser tuberc*

The **head** of the humerus (fig. 376), nearly hemispherical in
directed upwards, medialwards, and a little backwards; it articulat

Fig. 376.—The upper end of the left humerus. Superior aspect.

the glenoid cavity of the scapula. The circumference of its articular
is slightly constricted, and is termed the *anatomical neck*, in contradis
to a constriction below the tubercles, which is called the *surgical neck* be
is frequently the seat of fracture.

The *anatomical neck* forms an obtuse angle with the body and is best
in the lower half of its circumference; in the upper half it is represent
narrow groove separating the head from the tubercles. It affords atta
to the articular capsule of the shoulder-joint, and is perforated by fo
for the transmission of blood-vessels.

The *greater tubercle* is lateral to the head and lesser tubercle. Its
surface is convex and marked by three impressions; the highest of thes
insertion to the Supraspinatus; the middle, to the Infraspinatus; the
and the bone for about 2·5 cm. distal to it, to the Teres minor. The
surface of the greater tubercle is convex, rough, and continuous with the
surface of the body.

The *lesser tubercle*, more prominent than the greater, is situated in
and is directed forwards and medialwards. On its upper and front pa

e *posterior surface* appears somewhat twisted, so that its upper part ted a little medialwards, its lower part backwards. Nearly the whole surface is covered by the lateral and medial heads of the Triceps brachii, mer arising above, the latter below the radial sulcus.

e lower end of the humerus is flattened from before backwards, and slightly forwards; it ends in a broad, articular surface which is divided o parts by a smooth ridge. Projecting on either side, at a higher level he articular surface, are the lateral and medial epicondyles. The *articular* (fig. 379) is curved slightly forwards, and its medial extremity is lower the lateral. The lateral portion of this surface is a smooth, rounded ce, named the *capitulum* of the humerus; it articulates with the cup- depression on the head of the radius, and is limited to the front and lower the bone. On the medial side of the capitulum is a shallow groove, in the medial margin of the head of the radius is received; above the art of the capitulum is a small depression, the *radial fossa*, which receives erior border of the head of the radius, when the forearm is flexed. The portion of the articular surface is named the *trochlea* or pulley; it ates with the semilunar notch of the ulna. Its central part consists of

FIG. 379.—The lower end of the left humerus. Inferior aspect.

groove which winds spirally from before backwards and lateralwards the lower end of the bone; the groove is deeper behind where it expands ppy the whole width of the trochlea. The medial margin of the trochlea minent, and forms about two-thirds of a circle, and the adjacent portion articular surface is convex from side to side on the front and lower the bone; on the posterior surface the convexity disappears. The l margin of the trochlea is rounded in front and below, where it is separated the capitulum by the groove which receives the margin of the head of the s; posteriorly the margin is sharp and prominent. Above the trochlea, nt, is a depression, the *coronoid fossa*, which receives the coronoid process ulna when the forearm is flexed, and above the trochlea, behind, is a triangular depression, the *olecranon fossa*, in which the summit of the non is received when the forearm is extended. These fossæ are separated one another by a thin lamina of bone, which is sometimes perforated e *supratrochlear foramen*; they are lined in the recent state by the rial stratum, and their margins afford attachment to the fibrous stratum, e articular capsule of the elbow-joint. The *lateral epicondyle* is small and culated, and curved a little forwards; it gives attachment to the radial eral ligament of the elbow-joint and to a tendon common to the origin of upinator and some of the extensor muscles of the forearm. The *medial* dyle, larger and more prominent than the lateral, is directed a little ards; it gives attachment to the ulnar collateral ligament of the elbow- to the Pronator teres, and to a common tendon of origin of some of the muscles of the forearm; the ulnar nerve and posterior ulnar recurrent run in a groove (*sulcus nervi ulnaris*) on the back of this epicondyle. upracondylar ridges end at the epicondyles.

Structure. The ends of the humerus consist of spongy substance, co a thin layer of compact bone (fig. 380); the body is composed of a compact bone, thicker at the c towards the extremities, and medullary canal extends throu length.

FIG. 380.—A longitudinal section through the head of the left humerus.

Ossification (figs. 381, 382).—T erus is ossified from eight centre each of the following parts: the head, the greater tubercle, the lesse the capitulum and lateral part of lea, the medial part of the trochle for either epicondyle. The centr body appears near the middle in t week of fœtal life, and gradually towards the ends, which at birth laginous. During the first year, occ before birth, ossification begins in during the third year in the tubercle, and during the fifth in th tubercle. By the sixth year the for the head and tubercles have form a single large epiphysis, whi with the body of the humerus al twentieth year. The lower end is o follows. At the end of the seco ossification begins in the capitul extends medialwards to form the c of the articular surface; the centre for the medial part of the trochlea about the twelfth year. Ossification begins in the medial epicondyle a fifth year, and in the lateral about the thirteenth or fourteenth year. Th for the lateral epicondyle fuses with those for the trochlea and capitulum. epiphysis thus formed unites with the body about the sixteenth or sev year; the medial epicondyle unites with the body about the eighteenth ye

Applied Anatomy.—The upper end of the humerus, though the first to ossi last to join the body, and the length of the bone is mainly due to growth from t epiphysial plate. Hence, in cases of amputation through the arm in young sub humerus continues to grow considerably, and the lower end of the bone, which ately after the operation was covered with a thick cushion of soft tissue, begins to thinning the soft parts and rendering the stump conical. This may necessi removal of about 5 cm. of the bone, and even after this operation a recurrenc conical stump may take place. The region of the upper epiphysis is a common the growth of tumours, both innocent and malignant.

The upper one-third of the humerus is best exposed through an incision al anterior border of the Deltoideus; the middle one-third by continuing this incision wards through the middle of the Brachialis between the parts of the muscle sup the musculocutaneous and radial nerves; the lower one-third by an incision al lateral epicondylar ridge.

Fractures of the humerus are common. This bone is probably more frequent tured by muscular action than any other long bone; it is usually the body of th just below the insertion of the Deltoideus, which is thus broken, and the accid been known to happen from throwing a stone or a hand-grenade. Fracture anatomical neck is a very rare accident. Fracture of the surgical neck of the bon uncommon; impaction may occur, or the upper end of the lower fragment may placed into the axilla and damage the vessels or nerves. The fracture simulates dis of the shoulder-joint, but can be distinguished by the fact that the head of the bone in its normal position and the greater tubercle still forms the most prominent poi shoulder. Separation of the upper epiphysis sometimes occurs in the young subj is marked by a characteristic deformity, the upper end of the diaphysis projecting at at the front of the joint a short distance below the coracoid process. In fractures upper end of the humerus, extension with the arm in the abducted position is ne so that should ankylosis take place the mobility of the scapula may be brought u use. In fractures of the body of the humerus the lesion may take place at any but appears to be more common in the lower than the upper part of the bone. Th of interest in connexion with these fractures are: (1) that the radial nerve may be as it lies in the groove on the bone, or may become involved in the callus w

Digitized by Arya Samaj Foundation Chennai and eGangotri

ently thrown out; and (2) the frequency of non-union, which is believed to be more in the humerus than in any other bone. The non-union is in some measure due difficulty in fixing the bone, since the upper end articulates with the movable and the body lies by the chest-wall which moves with each respiration. Again, s attached to the entire circumference of the bone and is liable to get between the ts, should there be any overlapping of the latter. The axillary (circumflex) nerve

The lines of attachment of the articular capsules are in blue.

injured by fractures of the upper end of the bone and the ulnar nerve by fracture medial epicondyle. In fractures of the lower end it is important to distinguish those that involve the elbow-joint and those that do not; the former are always as they may lead to impairment of the utility of the limb; they include the ed fracture and oblique fractures which involve the articular surface. Those which involve the joint are the transverse fracture above the epicondyles, and the so-called bear fracture, where the tip of the medial epicondyle is broken off, generally by violence.

THE RADIUS

e radius (figs. 383 and 384) is situated on the lateral side of the forearm. a long bone, prismoid in form and slightly curved longitudinally. Its end is small, and forms only a small part of the elbow-joint; its lower s large, and forms a large part of the wrist-joint.

e upper end of the radius consists of a head, neck, and tuberosity. The disc-shaped, and on its proximal surface is a shallow cup for articulation he capitulum of the humerus. The circumference of the head is smooth; road medially where it articulates with the radial notch of the ulna, and w in the rest of its extent which is embraced by the annular ligament. ead is supported on a round, smooth, and constricted *neck*. Below the

medial part of the neck is an eminence, the *radial tuberosity*, the a
which is divided into a dorsal rough portion for the insertion of th
of the Biceps brachii, and a volar smooth portion on which a bursa is i
between the tendon and the bone.

The **body** or **shaft** of the radius is prismoid in form, narrower at
below, and slightly curved, so as to be convex laterally. It has thre
and three surfaces.

The *volar or anterior border* separates the volar from the lateral
and extends from the lower part of the tuberosity above, to the ante
of the base of the styloid process below. Its upper part is promin
from its oblique direction has been named the *oblique line*; it gives
the Flexor digitorum sublimis and Flexor pollicis longus; the surfa
the line gives insertion to part of the Supinator. The middle part of t
border is indistinct. The lower part is prominent, and gives insertio
Pronator quadratus, and attachment to the dorsal carpal ligament;
in a small tubercle, into which the tendon of the Brachioradialis is ins

The *dorsal or posterior border* separates the dorsal from the lateral
it is well-marked only in the middle one-third of the bone.

The *interosseous crest* or *medial border* separates the volar from th
surface, and gives attachment to the antibrachial interosseous me
(fig. 388); it begins above, at the posterior part of the tuberosity, and i
part is indistinct. It becomes sharp and prominent as it descen
divides below into two ridges which are continued to the volar and dorsal
of the ulnar notch; to the dorsal ridge the lower part of the anti
interosseous membrane is attached, and on the triangular surface
the ridges a part of the Pronator quadratus is inserted.

The *volar or anterior surface* is concave in its upper three-fourths, a
origin to the Flexor pollicis longus; its lower one-fourth is broad and
affords insertion to the Pronator quadratus. A prominent ridge li
insertion of the Pronator quadratus below, and between this ridge and th
articular surface is a triangular rough surface for the attachment of th
radiocarpal ligament. At the junction of the upper with the middle o
of the volar surface is the nutrient canal, directed obliquely upwards.

The *dorsal surface* is convex and smooth in the upper one-third of its
and covered by the Supinator. Its middle one-third, broad and
concave, gives origin to the Abductor pollicis longus above, and the E
pollicis brevis below. Its lower one-third, broad and convex, is covered
tendons of the muscles which subsequently run in the grooves on the lo
of the bone.

The *lateral surface* is convex; its upper part gives insertion to the Sup
near its centre is a rough ridge, for the insertion of the Pronator te
contact with its lower part are the tendon of the Brachioradialis a
tendons of the Extensores carpi radialis longus et brevis.

The **lower end** of the radius is large and is provided with two ar
surfaces—one below, for the carpus, and another at the medial side,
ulna. The carpal articular surface (fig. 389) is triangular, concave, smoo
divided by a slightly-marked anteroposterior ridge into two parts. The
triangular part, articulates with the navicular bone; the medial, quadr
part, with the lunate bone. The ulnar articular surface is called the *ulna*
(sigmoid cavity); it is narrow and concave, and articulates with the
the ulna. These two articular surfaces are separated by a prominent r
which the base of the triangular articular disc is attached; this disc se
the radiocarpal joint from the distal radio-ulnar joint. The lower end
bone has three non-articular surfaces—volar, dorsal, and lateral. Th
surface, rough and irregular, affords attachment to the volar radi
ligament. The *dorsal surface* is convex; it affords attachment to the
radiocarpal ligament, and is marked by three grooves. Enumerate
the lateral side, the first groove is broad, but shallow, and subdivided
faint vertical ridge; the lateral part transmits the tendon of the Ex
carpi radialis longus, the medial, the tendon of the Extensor carpi radialis
The second groove, deep and narrow, is bounded laterally by a sharp
it runs obliquely downwards and lateralwards, and transmits the ten
the Extensor pollicis longus. The third groove is broad, for the passage

The line of attachment of the articular capsule of the wrist-joint is in blue.

ructure.—The structure of the radius is like that of the other long bones.

ssification (figs. 385, 386).—The radius is ossified from three centres: one for ody, and one for either end. That for the body appears near the middle, e eighth week of fœtal life. About the close of the second year, ossification s in the lower end; and at the fifth year, in the upper end. The upper epi- s fuses with the body at the age of seventeen or eighteen years, the lower the age of twenty. An additional centre sometimes appears in the radial ssity about the fourteenth or fifteenth year.

THE ULNA

e ulna (figs. 383 and 384) is placed at the medial side of the forearm, el with the radius. The upper end is thick and strong, and forms a part of the elbow-joint; the body or shaft diminishes in size from above wards; the lower end is small, and is excluded from the wrist-joint by interposition of a triangular articular disc.

coronoid process. It is concave from above downwards and its deepest is constricted and sometimes crossed by a groove; it is divided into a al and a lateral portion by a smooth ridge running from the beak of olecranon to the apex of the coronoid process. The medial portion is larger, and is slightly concave transversely; the lateral is convex above, ly concave below.

The *radial notch* (lesser sigmoid cavity) (fig. 387) is an oblong, articular ssion on the lateral side of the coronoid process, for the reception of the nferential articular surface of the head of the radius. It is concave from e backwards, and its volar and dorsal margins serve for the attachment of annular ligament.

The body or shaft of the ulna, at its upper part, is prismoid in form, and d, with its convexity directed dorsalwards and lateralwards; its central part smoid and straight; its lower part is rounded and bent a little lateralwards body tapers gradually from above downwards, and has three borders and surfaces.

The *volar or anterior border* separates the volar from the medial surface; gins above at the prominent medial angle of the coronoid process, and below in front of the styloid process. Its upper part, well defined, and iddle portion, smooth and rounded, give origin to the Flexor digitorum dus; its lower part forms minent ridge for the origin e Pronator quadratus.

The *dorsal border* is subneous, and separates the al from the dorsal surface; gins above at the apex of triangular area on the um of the olecranon, runs st downwards and lateralls, and ends below at back of the styloid process.

Its upper three-fourths well marked and give chment to an aponeurosis which affords a common origin to the Flexor ulnaris, the Extensor carpi ulnaris, and the Flexor digitorum profundus; wer one-fourth is smooth and rounded.

Fig. 388.—A transverse section through the left radius and ulna, showing the attachment of the antibrachial interosseous membrane. Superior aspect.

The *interosseous crest* or *lateral border* separates the volar from the dorsal ce and gives attachment to the antibrachial interosseous membrane 388); it begins above by the union of two lines, which converge from the of the radial notch and form the sides of a triangular area for the origin rt of the Supinator. The crest ends below at the head of the ulna; its r part is sharp and prominent, its lower, smooth and rounded.

The *volar surface* is broader above than below; its upper three-fourths are ave and give origin to the Flexor digitorum profundus; its lower one-fourth vered by the Pronator quadratus and is separated from the rest of the ce by a ridge which is directed obliquely downwards and medialwards, marks the extent of origin of the Pronator quadratus. At the junction of upper with the middle one-third of the volar surface is the nutrient canal, ted obliquely upwards.

The *dorsal surface*, directed dorsalwards and lateralwards, is broad above; ex and somewhat narrower in the middle; narrow and rounded below. its upper part is an oblique ridge which runs downwards from the dorsal of the radial notch to the dorsal border; the upper part of the ridge affords chment to the Supinator, and the triangular surface above the ridge gives rtion to the Anconæus. Below this ridge the dorsal surface is subdivided *perpendicular line*, into a medial and a lateral portion: the medial part is h, and covered by the Extensor carpi ulnaris; the lateral part gives s from above downwards to the Abductor pollicis longus, the Extensor cis longus, and the Extensor indicis proprius.

The *medial surface* is broad and concave above, narrow and convex below. upper three-fourths give origin to the Flexor digitorum profundus; its er one-fourth is subcutaneous.

The lower end of the ulna is small, and has two eminences; the and larger is termed the head of the ulna; the medial, narrower projecting, the styloid process. On the *head* is an articular surface; part of this surface, of a semilunar form (fig. 389), is directed do and comes into contact with the upper surface of the triangular arti which separates the ulna from the radiocarpal joint; the remaining directed lateralwards, is narrow and convex, and is received ulnar notch of the radius. The *styloid process* projects from the me dorsal part of the bone; it descends a little lower than the head, rounded apex affords attachment to the ulnar collateral liga

Fig. 389.—The lower ends of the left radius and ulna. Inferior aspect.

the wrist-joint. The head is separated from the styloid process, belo depression for the attachment of the apex of the triangular articular di behind by a groove for the tendon of the Extensor carpi ulnaris.

Structure.—The structure of the ulna is similar to that of the oth bones.

Ossification (figs. 390, 391).—The ulna is ossified from three centres: for the body, the lower end, and the top of the olecranon. Ossificatio near the middle of the body, about the eighth week of fœtal life, and soon through its greater part. About the fourth year, the centre for the lo appears in the middle of the head, and extends into the styloid process. the tenth year, a centre appears in the olecranon and forms a thin scale top of this process, the chief part of the process being formed by an upward ex of the body; sometimes the upper part of the olecranon is ossified from two The upper epiphysis joins the body about the sixteenth, the lower about the tw year.

Applied Anatomy.—When indirect force is applied to the forearm the radius gives way, though both bones may suffer. Fractures from indirect force genera place somewhere about the middle of the bones, while those from direct violen occur at any part, but are most frequent in the lower half of the bones. The fract usually transverse, but may be more or less oblique. A point of interest in co with these fractures is the tendency for the two bones to unite across the inter membrane; the limb should therefore be put up in a position midway between sup and pronation, which is not only the most comfortable position, but also separ bones most widely from each other. Anterior and posterior splints are applied cases, and should be rather wider than the limb, so as to prevent any side pres the bones.

The special fractures of the ulna are: (1) Fracture of the olecranon, which is caused by direct violence, by falls on the elbow with the forearm flexed, but occas by muscular action in sudden contraction of the Triceps brachii; the most comm of this fracture is at the constricted portion where the olecranon joins the body bone, and the fracture is usually transverse; but any part may be broken, and eve shell may be torn off. Fractures from direct violence are occasionally comminu the fibrous structures around the process are not torn, the displacement is slight wise the olecranon may be drawn up for a very considerable distance. (2) Fractur coronoid process may occur as a complication of dislocation backwards of the bones forearm, but it is doubtful if it ever takes place as an uncomplicated injury. (3 tures of the body of the ulna may occur at any point, but usually take place at co

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the middle of the bone. They are generally the result of direct violence, but may as a complication of dislocation of the radius. (4) The styloid process may be d off by direct violence.
e ulna may be exposed in its whole length by an incision along its dorsal border.

FIG. 391.—The epiphysial lines of the left ulna in a young adult. Lateral aspect.

The lines of attachment of the articular capsules are in blue.

0.—A plan of the ossification of the ulna. From three centres.

ctures of the radius may consist of: (1) Fracture of the head of the bone; this for ost part takes place in conjunction with some other lesion, but may occur as an plicated injury. (2) Fracture of the neck also may occur, but is usually compli- with other injury. (3) Fractures of the body of the radius are very common, and e place at any part of the bone. In fracture of the upper one-third of the body— s to say, above the insertion of the Pronator teres—the displacement is very great. pper fragment is strongly supinated by the Biceps and Supinator, and flexed by the s; while the lower fragment is pronated and drawn towards the ulna by the two ors. If such a fracture be put up in the ordinary position, midway between ation and pronation, the bone will unite with the upper fragment in a position of ation, and the lower one in the mid-position, and thus considerable impairment movement of supination will result; the limb should therefore be put up with the m supinated. (4) The most important fracture of the radius is that of the lower (Colles's fracture). The fracture is transverse, and generally takes place about m. from the lower end. It is caused by falls on the palm of the hand, and is ry of advanced life, occurring more frequently in the female than in the male. In quence of the manner in which the fracture is caused, the upper fragment is driven e lower, and impaction commonly is the result; excess of violence may, however, pact, the lower fragment being split into two or more pieces, so that no fixation r. Separation of the lower epiphysis of the radius may take place in the young. injury and Colles's fracture may be distinguished from other injuries in this neigh- d—especially dislocation of the wrist, with which they are liable to be confounded bserving the relative positions of the styloid processes of the ulna and radius. In tural conditions of parts, with the arm hanging by the side, the styloid process of dius is on a lower level than that of the ulna. After fracture or separation of the ns the styloid process of the radius is on the same level as, or on a higher level that of the ulna, whereas it would be unaltered in position in dislocation. Reduc- n the case of Colles's fracture is usually easily effected by traction on the hand, the

limb being subsequently splinted with the hand deflected towards the ulnar side. plete reduction is most important in this fracture, since any imperfection leads ment of mobility and function.

The upper one-third of the radius is exposed through an incision along the margin of the Brachioradialis, and then along the oblique line of the Radius. The containing the deep branch (posterior interosseous branch) of the radial nerve is lateralwards, and the Flexores digitorum sublimis et profundus medialwards bone.

THE SKELETON OF THE HAND

The skeleton of the hand (figs. 392, 393) consists of three segments: carpal or wrist bones ; (2) the metacarpal bones or bones of the palm; the phalanges or bones of the digits.

The Carpal Bones (Ossa Carpi)

The carpal bones, eight in number, are arranged in two rows. of the proximal row, from the radial to the ulnar side, are named the na lunate, triquetral, and pisiform bones ; those of the distal row, in th order, are the greater multangular, lesser multangular, capitate, and bones.

The Common Characteristics of the Carpal Bones

Each bone (excepting the pisiform) presents six surfaces. Of th *volar or anterior* and the *dorsal or posterior surfaces* are rough, for liga attachment ; the dorsal surfaces are the broader, except in the navic lunate bones. The *proximal or superior*, and *distal or inferior surf* articular, the proximal generally convex, the distal concave ; the *med lateral surfaces* are also articular where they are in contact with co bones, elsewhere they are rough and tuberculated.

The Navicular Bone (Os Naviculare Manus)

The navicular bone (fig. 394), the largest of the proximal row, has re its name from its fancied resemblance to a boat. It is situated at the side of the carpus, its long axis being from above downwards, lateral and forwards. The *proximal surface*, convex, smooth, and of triangular

Fig. 394.—The left navicular bone.

articulates with the lower end of the radius. The *distal surface*, di downwards and backwards, is also smooth, convex, and triangular divided by an indistinct ridge into a lateral part which articulates w greater multangular bone, and a medial with the lesser multangular

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

he *dorsal surface* is a narrow, rough groove which serves for the attachment ments. The *volar surface* is concave above, but elevated at its lower lateral part into a rounded *tubercle*, which is directed forwards and gives hment to the transverse carpal ligament and sometimes to a few fibres e Abductor pollicis brevis. The *lateral surface*, rough and narrow, gives hment to the radial collateral ligament of the wrist. On the *medial ce* are two articular facets; of these, the proximal is flat and crescentic hape, and articulates with the lunate bone; the distal is concave, and s with the lunate bone a concavity for the head of the capitate bone.

The Lunate Bone (Os Lunatum)

he lunate or semilunar bone (fig. 395), distinguished by its deep con- y and crescentic outline, is situated in the centre of the proximal row e carpus, between the navicular and triquetral bones. The *proximal ce*, convex and smooth, articulates with the radius. The *distal surface* is

Fig. 395.—The left lunate bone.

ly concave from before backwards; it articulates with the head of the tate bone by a large lateral facet, and with the hamate bone by a narrow, ial one. The *dorsal* and *volar surfaces* are rough, for the attachment of ments, the dorsal being the smaller. On the *lateral surface* is a semilunar for articulation with the navicular bone, and on the *medial surface* a rilateral facet for the triquetral bone.

The Triquetral Bone (Os Triquetrum)

he triquetral or cuneiform bone (fig. 396) may be distinguished by its midal shape, and by an oval, isolated facet for articulation with the pisiform

Fig. 396.—The left triquetral bone.

Fig. 397.—The left pisiform bone.

ne. It is situated at the ulnar side of the proximal row of the carpal bones its long axis from above downwards and medialwards. The *proximal ce* presents a medial rough non-articular portion, and a lateral convex oth portion which articulates with the triangular articular disc of the wrist. *distal surface*, directed lateralwards, is concave, sinuously curved, and oth for articulation with the hamate bone. The *dorsal surface* is rough the attachment of ligaments. The *volar surface* displays, on its medial part, oval facet for articulation with the pisiform bone; its lateral part is rough

for ligamentous attachment. The *lateral surface*, or base of the pyr marked by a flat, quadrilateral facet for articulation with the lunat The *medial surface*, or summit of the pyramid, is pointed and gives att to the ulnar collateral ligament of the wrist.

The Pisiform Bone (Os Pisiforme)

The **pisiform bone** (fig. 397) is situated in front of the triquetral bo may be known by its small size, and by its presenting a single, oval f articulation with that bone. This facet is on the *dorsal surface* of th and its long axis is directed distalwards and lateralwards. The *volar* is round and rough, and gives attachment to the Flexor carpi ulnari *medial surface* gives attachment to the Abductor digiti quinti and the carpal ligament; the pisometacarpal ligament is attached to the dis of this surface. On the volar and lateral surfaces is an oblique line o the distal part of which gives attachment to the volar carpal ligament distal part of the bone projects beyond the articular surface and p a tubercle for the attachment of the pisohamate ligament.*

The Greater Multangular Bone (Os Multangulum Majus)

The **greater multangular bone or trapezium** (fig. 398) may b tinguished by a deep groove on its volar surface. It is situated at the side of the carpus, between the navicular and first metacarpal bones *proximal surface* is directed upwards and medialwards; medially it is

Fig. 398.—The left greater multangular bone.

and articulates with the navicular bone; laterally it is rough and conti with the lateral surface. The *distal surface* is oval, concave from side to convex from before backwards, so as to form a saddle-shaped surfac articulation with the base of the first metacarpal bone The *dorsal* is rough. The *volar surface* is narrow and rough. At its upper part is a groove, running from above downwards; it transmits the tendon of the carpi radialis, and is bounded laterally by a ridge which affords attac to the transverse carpal ligament, and gives origin to the Opponens p Abductor pollicis brevis, and Flexor pollicis brevis. The *lateral surf* broad and rough for the attachment of ligaments. On the *medial* are two facets; a proximal, large and concave, articulates with the multangular bone; a distal, small and oval, with the base of the metacarpal bone.

The Lesser Multangular Bone (Os Multangulum Minus)

The **lesser multangular or trapezoid bone** (fig. 399) is the smallest in the distal row. It may be known by its wedge-shaped form, the thick of the wedge constituting the dorsal surface; and by its having four art

s separated by sharp edges. The *proximal surface*, smaller, quadrilateral, slightly concave, articulates with the navicular bone. The large *distal* ce articulates with the proximal end of the second metacarpal bone; convex from side to side, concave from before backwards. The *dorsal*

Fig. 399.—The left lesser multangular bone.

olar surfaces are rough for the attachment of ligaments, the former being larger. The *lateral surface* is convex, and articulates with the greater angular bone. The *medial surface* is concave and smooth in front, for ulation with the capitate bone; rough behind, for the attachment of an sseous ligament.

The Capitate Bone (Os Capitatum)

The capitate bone or os magnum (fig. 400) is the largest of the carpal bones, occupies the centre of the wrist. It presents a rounded proximal portion, head, which is received into the concavity formed by the navicular and te bones; a constricted portion, the neck; and a distal part, the body.

Fig. 400.—The left capitate bone.

proximal surface is round, smooth, and articulates with the lunate bone. *distal surface* is divided by two ridges into three facets, for articulation with second, third, and fourth metacarpal bones, that for the third being the gest. The *dorsal surface* is broad and rough. The *volar surface* is narrow, jecting and rough; it gives attachment to ligaments and to the oblique t of the Adductor pollicis. The *lateral surface* articulates, by a small facet its volar distal angle, with the lesser multangular bone; dorsal to this facet is ugh depression for the attachment of an interosseous ligament. Proximal this is a deep, rough groove, forming part of the neck, and serving for the achment of ligaments; it is bounded proximally by a smooth, convex face, for articulation with the navicular bone. The *medial surface* articulates the hamate bone by a smooth, oblong facet which occupies the dorsal proximal parts of this surface; its volar part is rough for the attachment interosseous ligament.

The Hamate Bone (Os Hamatum)

The **hamate or unciform bone** (fig. 401) may be readily dist by its wedge-shaped form, and the hook-like process which projects volar surface. It is situated at the medial and distal part of t with its base directed distally, and its apex proximally and latera *proximal surface* or apex of the wedge is convex, smooth, and a with the lunate bone. The *distal surface* articulates with the fo fifth metacarpal bones, by concave facets which are separated by

Fig. 401.—The left hamate bone.

ridge. The *dorsal surface* is triangular, and rough for ligaments. F distal and medial part of the *volar surface* a curved, hook-like proc *hamulus*, is directed forwards and lateralwards. This process gives atta by its apex, to the transverse carpal ligament and the Flexor carpi by its medial surface to the Flexor brevis and Opponens digiti qui lateral side is grooved for the passage of the flexor tendons into the the hand. The *medial surface* articulates with the triquetral bone oblong, obliquely-cut facet. The proximal and dorsal parts of the *lateral* articulate with the capitate bone; the rest of the surface is rough attachment of ligaments.

The Metacarpal Bones (Ossa Metacarpi)

The **metacarpal bones** (figs. 392, 393), five in number, are enu from the lateral side.

The Common Characteristics of the Metacarpal Bones

Each metacarpal bone has a body, a base or proximal end, and a h distal end.

The **body** of each bone is prismoid in form, and curved, so as to be c longitudinally behind, concave in front. It has three surfaces: medial, l and dorsal. The *medial* and *lateral surfaces* are concave, for the attac of the Interossei, and separated from one another by a prominent volar The *dorsal surface* presents in its distal two-thirds a smooth, triangular, fl area which is covered, in the recent state, by the tendons of the extensor m This surface is bounded by two lines, which commence in small tu situated at the sides of the head, and converge and meet some distance the centre of the bone to form a ridge which is continued to the base. ridge separates two sloping surfaces for the attachment of the Inte dorsales. To the tubercles at the head are attached the collateral liga of the metacarpophalangeal joints.

The **base** is of a cuboidal form, and broader behind than in front: it arti with one or more of the carpal bones, and with the contiguous meta bones; its *dorsal* and *volar surfaces* are rough, for the attachment of ligam

The **head** presents an oblong surface markedly convex from before wards, less so transversely; it articulates with the proximal phalan

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

broader, and extends farther proximalwards on the dorsal surface, and its transverse diameter is the shorter. On either side of the base is a deep depression, and behind this a tubercle for the attachment of one of the collateral ligaments of the metacarpophalangeal joint. The *dorsal surface*, broad and flat, supports the extensor tendons; the *volar surface* is grooved for the flexor tendons, and marked on either side by an articular surface continuous with the terminal articular surface.

The Characteristics of the Individual Metacarpal Bones

The **first metacarpal bone** (fig. 402), shorter and stouter than the others, differs from the second, and its volar surface is directed medialwards. The shaft is flattened and broad on its dorsal surface, but does not present the ridge which is found on the other metacarpal bones; its volar surface is concave from above downwards. The Opponens pollicis is inserted into its radial border; the lateral head of the first Interosseus dorsalis arises from its ulnar border. The *base* presents a concavoconvex surface, for articulation with the greater multangular bone; it has facets on its sides, but on its lateral side is a tubercle for the insertion of the Abductor pollicis longus. The *head* is less convex than the heads of the other metacarpal bones, and broader from side to side than from before backwards. On its volar surface are two tubular eminences, of which the lateral is the larger; on these surfaces sesamoid bones

Fig. 402.—The first left metacarpal bone.

The **second metacarpal bone** (fig. 403) is the longest, and its base the largest, of the four remaining bones. Its *base* is deeply grooved, and medial to the groove is a prominent ridge. The base presents four articular facets: three on the proximal, and one on the medial surface. Of the facets

Fig. 403.—The second left metacarpal bone.

on the proximal surface, the intermediate is the largest and is concave
to side, convex from before backwards, for articulation with the la
angular bone; the lateral is small, flat and oval for articulation with t
multangular bone; the medial, on the summit of the ridge, is long a
for articulation with the capitate bone. The facet on the medial side
with the third metacarpal bone. The Extensor carpi radialis longus
on the lateral part of the dorsal surface, and the Flexor carpi radi
volar surface, of the base.

The **third metacarpal bone** (fig. 404) is a little smaller than th
On the lateral side of the dorsal part of its *base* is a pyramidal emi
styloid process; immediately distal to this is a rough surface for the at
of the Extensor carpi radialis brevis. The proximal articular facet i
dorsally, and articulates with the capitate bone. On the lateral
smooth, concave facet for articulation with the second metacarpal b
on the medial side two small oval facets for the fourth metacarpal b

Fig. 405.—The fourth left metacarpal bone.

Fig. 406.—The fifth le carpal bone.

The **fourth metacarpal bone** (fig. 405) is shorter than the third.
is small and quadrilateral; on its proximal surface are two facets, a large
one for articulation with the hamate bone, and a small one at the dorsa
angle for the capitate bone. On the lateral side are two oval face
articulation with the third metacarpal bone; and on the medial side, a
concave facet, for the fifth metacarpal bone.

The **fifth metacarpal bone** (fig. 406) has two facets on its *base*; t
its proximal surface is saddle-shaped, and articulates with the hamate
that on the lateral side articulates with the fourth metacarpal bone
medial side is a tubercle for the insertion of the tendon of the Extens
ulnaris. The dorsal surface of the body is divided by an oblique ridge,
extends from near the medial side of the base to the lateral side of the
The lateral part of this surface serves for the attachment of the fourth
osseus dorsalis; the medial part, smooth and triangular, is covered
extensor tendons of the little finger.

The Phalanges of the Hand (Phalanges Digitorum Manus)

The **phalanges** are fourteen in number, three for each finger, and t
the thumb. Each consists of a body and two ends. The *body* tapers t
its distal end, and its dorsal surface is convex; its volar surface is c
longitudinally, and flat from side to side; its sides are marked by rough
which give attachment to the fibrous sheaths of the flexor tendons.

ual ends of the bones of the first row present oval, concave articular ces, broader from side to side than from before backwards. On the nal end of each of the bones of the second and third rows are two con- ies separated by a median ridge. The *distal ends* are smaller than the nal, and each terminates in two condyles separated by a shallow groove; rticular surface extends farther on the volar than on the dorsal surface, a tion best marked in the bones of the first row.

he *ungual phalanges* are convex on their dorsal, and flat on their volar ces; they are recognised by their small size, and by a rough, elevated e of a horseshoe form on the volar surface of the distal end of each, which s to support the sensitive pulp of the finger.

The Ossification of the Bones of the Hand

he **carpal bones** are each ossified from a single centre, and ossification proceeds following order (fig. 407): in the capitate and hamate bones, during the ear; in the triquetral bone, during the third year; in the lunate and greater

angular bones, during the fifth year; in the navicular bone, during the sixth r; in the lesser multangular bone, during the eighth year; and in the pisiform about the twelfth year.

ccasionally an additional bone, the *os centrale*, is found between the navicular, multangular, and capitate bones. During the second month of fœtal life represented by a small cartilaginous nodule, which usually fuses with the laginous navicular. Sometimes the styloid process of the third metacarpal e is detached and forms an additional ossicle.

The **metacarpal bones** are each ossified from two centres; a primary for the body, and a secondary or epiphysial centre for the base or proximal the first and for the head or distal end of each of the other four.* The first carpal bone is therefore ossified in the same manner as the phalanges, and has led some anatomists to regard the thumb as being made up of three phalanges and not of a metacarpal bone and two phalanges. Ossification begins in the of the body about the eighth or ninth week of fœtal life, the centres for the and third metacarpal bones being the first, and that for the first metacarpal the last, to appear. About the third year the base of the first metacarpal and the heads of the other metacarpal bones, begin to ossify; they unite with bodies about the twentieth year.

The **phalanges** are each ossified from two centres; a primary centre body, and a secondary or epiphysial centre for the proximal extremity. Ossification begins in the body about the eighth week of fœtal life. The epiphyses for the of the first row of phalanges appear between the third and fourth years, and for the second and third rows of phalanges a year later. All unite with the between the eighteenth and twentieth years.

In the ungual phalanges the centres for the bodies appear at the distal of the phalanges, instead of at the middle of the bodies, as in the other phalanges. Moreover, of all the bones of the hand, the ungual phalanges are the last ossify.

Applied Anatomy.—The use of X-rays has shown that the carpal bones are frequently fractured than was formerly supposed. When a single bone is broken usually the navicular or the capitate (more frequently the former) and the fracture at right angles to the long axis of the bone. There are two diseases of the metacarpal bones and phalanges which require special mention on account of their frequency. One is tuberculous dactylitis, consisting of a deposit of tuberculous matter in the medullary canal, expansion of the bone, with subsequent caseation and suppuration. The other is chondroma, which is perhaps more commonly found in connexion with metacarpal bones and phalanges than with any other bones. The tumours are multiple, and spring from beneath the periosteum about the epiphysial plate. In arthritis small symmetrical bony outgrowths known as "Heberden's nodes," often on the dorsal aspects of the terminal joints of the fingers, with radial deflection of terminal phalanges in advanced cases. These nodes are usually painless, but inconvenience by limiting the mobility of the finger-tips.

THE BONES OF THE INFERIOR EXTREMITY

The Hip-Bone (Os Coxæ)

The **hip-bone** (os innominatum) (figs. 408, 409) is a large, flattened, irregularly shaped bone, constricted in the centre and expanded above and below. It articulates in front with the bone of the opposite side, and the two bones form the pelvic girdle or girdle of the inferior extremity. The hip-bone consists of three parts, the ilium, ischium, and os pubis, which are distinct from one other in the young subject, but are united in the adult; the union of the three parts takes place in and close to a large cup-shaped articular cavity, the acetabulum, which is situated near the middle of the outer surface of the bone.

The **ilium** (os ilii) so named because it supports the flank, is the broad, expanded portion of the hip-bone which extends upwards from the acetabulum. It is divisible into two parts, the body and the ala, which are separated on the internal surface of the bone by a curved line, the *arcuate line*, and on the external surface by the upper part of the margin of the acetabulum.

The **body** of the ilium forms rather less than two-fifths of the acetabulum. Its *external surface* is partly articular, partly non-articular; the articular

* Allen Thomson (*Journal of Anatomy and Physiology*, vol. iii. 1869) pointed out that the first metacarpal bone is often developed from three centres; that is to say, there is a second centre for the distal end, forming a distinct epiphysis visible at the age of seven or eight. He also stated that there are traces of a proximal epiphysis in the second metacarpal bone.

e *internal surface* (fig. 409) of the ala is bounded above by the crest; by the arcuate line; in front and behind by the anterior and posterior rs. The tendon of the Psoas minor is inserted into the arcuate line. nterior part of the internal surface, smooth and concave, is termed the ossa; it gives origin to the Iliacus, and is perforated posteriorly by a nt canal. Behind the iliac fossa is a rough surface, divided into a superior an inferior portion. The inferior portion or *auricular surface*, so called its resemblance in shape to the auricula or pinna, articulates with a r surface on the side of the sacrum. The superior portion, known as the *tuberosity*, is elevated and rough, for the attachment of the short posterior liac ligament; it is continuous above and behind with the inner lip e iliac crest, and here it gives origin to the Sacrospinalis. Below and nt of the auricular surface is the *pre-auricular sulcus*, more commonly nt and better marked in the female than in the male; the pelvic portion anterior sacro-iliac ligament is attached to this sulcus.

e *crest* of the ilium is convex in its general outline but is sinuously curved, concave inwards in front, and outwards behind. It is thinner at the than at the extremities, and it ends in the anterior and posterior superior pines. The surface of the crest is divided into an external and an internal d an intermediate line; there is a prominent tubercle on the external ut 5 cm. behind the anterior superior iliac spine. To the external lip tached, from before backwards, the Tensor fasciæ latæ, Obliquus us abdominis, and Latissimus dorsi, and along its whole length the hata; to the intermediate line the Obliquus internus abdominis; to ternal lip, the Transversus abdominis, Quadratus lumborum, Sacro-s, Iliacus, and the fascia iliaca.

e *anterior border* of the ala presents two projections, separated by a notch. per projection, at the junction of the crest and anterior border, is called *nferior superior iliac spine*; its outer border gives attachment to the fascia and the Tensor fasciæ latæ; its inner border, to the Iliacus; its extremity attachment to the inguinal ligament, and origin to the Sartorius. Beneath me is a notch from which the Sartorius takes origin and across which teral femoral cutaneous nerve passes. Below the notch is the *anterior r iliac spine* which gives attachment to the straight tendon of the Rectus s and to the iliofemoral ligament of the hip-joint. Medial to the anterior r iliac spine is a broad, shallow groove, over which the Iliacus descends the thigh. This groove is bounded medially by the *iliopectineal eminence*, marks the union of the ilium and the os pubis.

e *posterior border* of the ala, shorter than the anterior, also presents two ctions, the *posterior superior* and *posterior inferior iliac spines*, separated otch. The former serves for the attachment of the long posterior sacro-ment; the latter corresponds with the posterior end of the auricular . Below the posterior inferior spine is a deep notch, the *greater sciatic*

e ischium (os ischii) forms the lowest part of the hip-bone. It is divisible body and a superior and an inferior ramus.

e body of the ischium enters into and constitutes a little more than ths of the acetabulum. Its *external surface* forms a part of the lunate e of the acetabulum and a portion of the acetabular fossa. Its *internal* e is a part of the wall of the lesser pelvis, and gives origin to some fibres e Obturator internus. Its *posterior surface* is convex, and covered by riformis muscle. Its *antero-inferior border* is thin, and forms a part e boundary of the obturator foramen; it ends above at the acetabular e. Its *lateral border* forms the posterior part of the rim of the acetabulum; e *medial border* a pointed triangular eminence, the *ischial spine*, extends rds and medialwards. The external surface of this spine gives attach-o the Gemellus superior; its internal surface to the Coccygeus, Levator d the pelvic fascia; its pointed extremity to the sacrospinous ligament. e spine is the *greater sciatic notch*, converted into a foramen by the inous ligament; this foramen transmits from the pelvis the Piriformis e, the superior and inferior glutæal vessels and nerves, the sciatic and or femoral cutaneous nerves, the internal pudendal vessels and pudendal

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

nerve, and the nerves to the Obturator internus and Quadratus fem
these, the superior glutæal vessels and nerve emerge above the Pirifo
other structures below it. Below the spine is the *lesser sciatic not*
converted into a foramen by the sacrotuberous and sacrospinous li
and transmits the tendon of the Obturator internus, the nerve which
that muscle, and the internal pudendal vessels and pudendal nerve.

The superior ramus of the ischium projects downwards and be
from the body and has three surfaces: external, internal, and posteri
external surface is quadrilateral in shape, and on its upper part is a
which lodges the tendon of the Obturator externus. Below, it is co
with the external surface of the inferior ramus; in front, it is limited
posterior margin of the obturator foramen; behind, a prominent
separates it from the posterior surface. In front of the latter ma
external surface gives origin to the Quadratus femoris, and to some
fibres of the Obturator externus; its lower part gives origin to a p
the Adductor magnus. The *internal surface* forms a part of the bony w
lesser pelvis. In front it is limited by the posterior margin of the o
foramen. Below and behind, it is bounded by a sharp ridge whic
attachment to the falciform process of the sacrotuberous ligament
anteriorly it gives origin to the Transversus perinæi superficialis a
Ischiocavernosus.

The *posterior surface* of the superior ramus forms a large swelli
tuberosity of the ischium, which consists of two portions: a lower, ro
angular part, and an upper, smoother, quadrilateral portion. Th
triangular portion is subdivided by a prominent longitudinal ridge i
parts; the lateral part gives attachment to the Adductor magnus, the
to the sacrotuberous ligament. The upper, quadrilateral portion is sub
into two areas by an oblique ridge which runs downwards and latera
from the upper and lateral area the Semimembranosus arises; from th
and medial area, the Semitendinosus and the long head of the Biceps fe

The inferior ramus is the thin, flattened part of the ischium, which
forwards from the superior ramus, and joins the inferior ramus of the os
the junction being indicated on the external surface by a raised li
external surface is uneven for the origin of the Obturator externus an
of the fibres of the Adductor magnus; its *internal surface* forms part
anterior wall of the pelvis and gives attachment to the Sphincter u
membranaceæ. The *lower border* of the inferior ramus is thick, rough, a
everted. It forms part of the outlet of the pelvis, and presents two
ridges and an intervening space. The ridges are continuous with simil
on the inferior ramus of the os pubis; to the outer is attached the dee
of the superficial perinæal fascia (fascia of Colles), and to the inner the
fascia of the urogenital diaphragm. When traced backwards these two
join; from the space just in front of their junction the Transversus p
superficialis takes origin, and in front of this the Ischiocavernosus a
crus penis vel clitoridis are attached. The *upper border* of the inferior
is thin, and forms part of the medial margin of the obturator foramen.

The os pubis, the anterior part of the hip-bone, is divisible into a
and a superior and an inferior ramus.

The body of the os pubis forms one-fifth of the acetabulum, contr
by its *external surface* both to the lunate surface and to the acetabular
Its *internal surface* enters into the formation of the wall of the lesser
Its *anterior surface* is marked by a rough eminence, the *iliopectineal em*
which indicates the junction of the ilium with the os pubis.

The superior ramus of the os pubis extends from the body to the m
plane, where it articulates with the superior ramus of the opposite os
It is conveniently described in two portions, viz. a medial flattened part
narrow lateral prismoid portion.

The *medial portion* of the superior ramus, formerly described as the
of the os pubis, is somewhat quadrilateral in shape, and has two surfaces
three borders. The *external surface* is directed downwards and lateral
and serves for the origin of various muscles. The Adductor longus
from the anterior and medial angle, immediately below the crest;
posteriorly, the Obturator externus, the Adductor brevis, and the upper

Gracilis take origin. The *internal surface*, convex from above downwards, ve from side to side, is smooth, and forms part of the anterior wall of esser pelvis. It gives origin to parts of the Levator ani and Obturator us, and attachment to the puboprostatic ligaments and to a few muscular prolonged from the bladder. On the *upper border* is a prominent tubercle, *bic tubercle* (pubic spine) which projects forwards and gives attachment inguinal ligament (Poupart's ligament). Passing upwards and lateral- from the pubic tubercle is a well-defined ridge, the *pecten pubis*, which a part of the brim of the lesser pelvis; to it are attached a portion of inguinal falx (conjoined tendon of Obliquus internus and Transversus), ligament (Gimbernat's ligament), and the reflected inguinal ligament ular fascia). Medial to the pubic tubercle is the *pubic crest*, which ds from the tubercle to the medial border of the bone; it affords attach- to the inguinal falx, and to the Rectus abdominis and Pyramidalis. oint of junction of the crest with the medial border of the bone is called *ngle*; a part of the superior crus of the subcutaneous inguinal ring is ed to it. The *medial border* is articular; it is oval, and is marked by or nine transverse ridges, or a series of nipple-like processes arranged s; they serve for the attachment of a thin layer of cartilage, which d to that of the opposite pubic bone by the interpubic fibrocartilaginous The *lateral border* presents a sharp margin, the *obturator crest*, which part of the circumference of the obturator foramen and affords attachment obturator membrane.

e *lateral portion* of the superior ramus has an internal and an external e, separated by the pecten pubis. The *internal surface* constitutes a part e anterior boundary of the lesser pelvis, and affords origin to some fibres Obturator internus. The *external surface* consists of an anterosuperior postero-inferior part, separated by a prominent ridge which extends the anterior margin of the acetabular notch to the pubic tubercle. The superior part, triangular in form, is limited above by the *iliopectineal ne* (p. 309), and is covered by the Pectineus. The postero-inferior also triangular in form, is directed towards the obturator foramen; on it is d, deep groove, the *obturator groove*, for the lodgment of the obturator s and nerve.

e **inferior ramus** of the os pubis is thin and flattened. It passes lateral- s and backwards from the medial part of the superior ramus, narrows ceedes and joins with the inferior ramus of the ischium below the obturator n. Its *external surface*, directed forwards and downwards, is rough e origin of the following muscles, viz.—the Gracilis along its medial r, a portion of the Obturator externus near the obturator foramen, and en these two muscles, the Adductores brevis et magnus, the former e more medial. The *internal surface*, directed backwards and upwards, th, and gives origin to the Obturator internus, and, close to the medial r, to the Sphincter urethræ membranaceæ. The *medial border* is thick, , and everted. It presents two ridges, separated by an intervening . The ridges extend downwards, and are continuous with similar ridges e inferior ramus of the ischium (p. 310); to the external is attached the cial perinæal fascia (fascia of Colles), and to the internal the inferior of the urogenital diaphragm. The *lateral border* is thin and sharp, part of the circumference of the obturator foramen, and gives attach- to the obturator membrane.

e **acetabulum** of the hip-bone (fig. 408) is a deep, cup-shaped, hemi- al depression, which looks downwards, lateralwards, and forwards. It is d above by the ilium, medially by the os pubis, posteriorly and below by the m; a little less than two-fifths is contributed by the ilium, a little more two-fifths by the ischium, and one-fifth by the os pubis. It is surrounded prominent, uneven rim, which is thick and strong above, and serves attachment of the glenoidal labrum (cotyloid ligament), which contracts fice of the acetabulum, and deepens the surface for articulation. It ts below, a deep notch, the *acetabular notch*, which is continuous with ly circular non-articular depression, the *acetabular fossa*, at the bottom e cavity; this fossa is perforated by apertures for vessels, and lodges a of fat. The notch is converted into a foramen by the transverse acetabular

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ligament, and through the foramen nutrient vessels and nerves enter the
the margins of the notch serve for the attachment of the ligamentum
The rest of the acetabulum consists of a horse-shoe shaped articular
the *lunate surface*, for articulation with the head of the femur.

The **obturator foramen** of the hip-bone is an aperture between the
and os pubis. In the male it is large and of an oval form, its longest
slanting obliquely from before backwards; in the female it is small
more triangular. It is bounded by a thin, uneven margin, to which the ob
membrane is attached, and it presents, superiorly, a deep groove, the
groove, which runs downwards and medialwards from the pelvis. This
is converted into a canal by a ligamentous band, which consists of a sp
part of the obturator membrane, and is attached to two tubercles:

FIG. 410.—A plan of the ossification of the hip-bone.

By eight centres { *Three primary, for the ilium, ischium, and os pubis.*
Five secondary.

The three primary centres unite through the Y-shaped piece about puberty.
Secondary centres appear about puberty, and unite about 25th year.

posterior obturator tubercle, just below the acetabular notch; the other
anterior obturator tubercle, on the obturator crest (p. 311) of the superior
of the os pubis. Through the canal the obturator vessels and nerve pa
of the pelvis.

Structure.—The thicker parts of the hip-bone consist of spongy sub
enclosed between two layers of compact bone; the thinner parts, as at the
of the acetabulum and centre of the iliac fossa, are usually semitransparent
composed entirely of compact bone.

Ossification (fig. 410).—The hip-bone is ossified from eight centres: three pri
one each for the ilium, ischium, and os pubis; and five secondary, one each f
crest of the ilium, the anterior inferior iliac spine (said to occur more freq
in the male than in the female), the tuberosity of the ischium, the pubic sym
(more frequent in the female than in the male), and one or more for the Y-sh
piece at the bottom of the acetabulum. The centres appear in the following o
in the ilium, immediately above the greater sciatic notch, about the eighth or
week of fœtal life; in the superior ramus of the ischium, about the third m
in the superior ramus of the os pubis, between the fourth and fifth months
birth, the iliac crest, the greater part of the acetabulum, the ischial tube

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

e inferior rami of the ischium and os pubis are cartilaginous. By the seventh
th year, the inferior rami of the os pubis and ischium are almost completely
d by bone. The three primary centres extend their growth into the bottom
e acetabulum, where they are separated from each other by a Y-shaped
n of cartilage which begins to ossify by two or more centres in the twelfth
One of these centres, the *os acetabuli*, forms the pubic part of the acetabulum
ses with the main parts of the bone about puberty. The ilium and ischium
become joined, and lastly the os pubis and ischium, through the intervention
Y-shaped portion. At about the age of puberty, ossification takes place in
of the remaining portions, and they join with the rest of the bone between the
eth and twenty-fifth years. Separate centres are frequently found for the
le, crest and angle of the os pubis, and the spine of the ischium.

The Pelvis

e pelvis, so called from its resemblance to a basin, is a massive bony
interposed between the movable segments of the vertebral column which
ports, and the lower limbs upon which it rests; it is composed of the

ig. 411.—The diameters of the superior aperture of the lesser pelvis (female).

ip-bones laterally and in front, and the sacrum and coccyx behind. It
vided into the greater and the lesser pelvis by an oblique plane passing
h the prominence of the sacrum behind, the arcuate line and pecten
laterally, and the upper margin of the symphysis pubis in front. The
nference of this plane is termed the *pelvic brim*.

he greater pelvis (pelvis major), the expanded portion of the cavity
e and in front of the pelvic brim, is formed on either side by the ilium
posteriorly by the base of the sacrum.

he lesser pelvis (pelvis minor) is that part of the pelvic cavity which lies
and behind the pelvic brim. Its bony walls are more complete than
of the greater pelvis. It possesses an inlet bounded by the superior
nference, an outlet bounded by the inferior circumference, and a
y.

he *superior circumference* forms the brim of the pelvis, the included space
called the *superior aperture* or *inlet* (fig. 411). The superior aperture
ewhat heart-shaped, obtusely pointed in front, and encroached upon
d by the forward projection of the promontory of the sacrum. It has
principal diameters: anteroposterior, transverse, and oblique. The
posterior or conjugate diameter extends from the sacrovertebral angle
the symphysis pubis; its average measurement is about 110 mm. in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

female. The *transverse diameter* extends from the middle of the brim side to the same point on the opposite side; its average measurement 135 mm. in the female. The *oblique diameter* extends from the iliac eminence to the opposite sacro-iliac articulation; its average measure is about 125 mm. in the female.

The *cavity* of the lesser pelvis is a short curved canal, considerably behind than in front. It is bounded in front and below by the pubic and symphysis; above and behind, by the pelvic surfaces of the sacrum coccyx; laterally by a smooth, quadrangular area of bone, formed inner surfaces of the body and superior ramus of the ischium and of of the ilium. It contains, in the recent subject, the sigmoid (pelvic rectum, urinary bladder, and some of the organs of generation. The is placed at the back of the pelvis, in the curve of the sacrum and the urinary bladder is in front, behind the pubic symphysis. In the the uterus and vagina lie between the rectum and the urinary bladder.

The *lower circumference* of the pelvis is very irregular; the space by it is named the *inferior aperture* or *outlet* (fig. 412), and is bounded

FIG. 412.—The diameters of the inferior aperture of the lessser pelvis (female)

by the apex of the coccyx, and laterally by the ischial tuberosities. eminences are separated by three notches: one in front, the *pubic arch*, by the convergence of the inferior rami of the ischium and os pubis on side. The other notches, one on either side, are formed by the sacrum coccyx behind, the ischium in front, and the ilium above: they are called *sciatic notches*; in the natural state they are converted into foramina by sacrotuberous and sacrospinous ligaments. When these ligaments have preserved, the inferior aperture of the pelvis is lozenge-shaped, and is bounded in front, by the arcuate pubic ligament and the inferior rami of the ossa pubis ischia; laterally, by the ischial tuberosities; behind, by the sacrotuberous ligaments and the tip of the coccyx.

The *anteroposterior diameter* of the inferior aperture of the pelvis extends from the apex of the coccyx to the lower part of the pubic symphysis measurement is from 90 to 115 mm. in the female. It varies with the of the coccyx, and is capable of increase or diminution, on account of mobility of that bone. The *transverse diameter*, measured between the posterior parts of the ischial tuberosities, is about 115 mm. in the female.*

Axes (fig. 413).—The axis of the superior aperture, *i.e.* a line at right angles to the plane of the superior aperture through its centre, is directed downwards

* The measurements of the pelvis given above are fairly accurate, but different figures given by various authors, no doubt mainly due to differences in the physique and stature of population from whom the measurements have been taken.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ackwards, and if the line be prolonged it passes through the umbilicus above he middle of the coccyx below. The axis of the inferior aperture is directed wards and slightly backwards; if prolonged upwards it touches the f the sacrum. The axis of the cavity—i.e. an axis at right angles to a of planes between and including of the superior and inferior res—is curved like the cavity this curve is parallel to that of rum and coccyx.

Fig. 413.—A median sagittal section through the pelvis.

sition of the pelvis (fig. 413).—erect posture, the pelvis is placed ly with regard to the trunk: the of the superior aperture forms the horizontal plane an angle of 50° to 60°, and that of the inferior re one of about 15°. The pelvic e of the symphysis pubis looks ds and backwards, the concavity sacrum and coccyx downwards orwards. The position of the in the erect posture may be ed by holding it so that the r superior iliac spines and the of the top of the symphysis pubis the same vertical plane.

ferences between the male emale pelves (figs. 414, 415, 416, 417).—The female pelvis is distinguished that of the male by its bones being more delicate and its depth less. The pelvis is less massive, and its muscular impressions are not so marked. are larger, their posterior borders are more rounded and less vertical. anterior iliac spines more widely separated; hence the greater lateral ance of the hips. The superior aperture of the lesser pelvis is larger in the

Fig. 414.—The female pelvis. Anterior aspect.

From a specimen in the museum of the Royal College of Surgeons of England.

than in the male; it is more nearly circular, and its obliquity is greater. vity is shallower and wider; the sacrum is shorter, wider, and its upper s less curved; the obturator foramina are triangular in shape and are e in size than in the male. The inferior aperture is larger, and the coccyx nsurvable. The pre-auricular sulci are more commonly present and better

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Occasionally the pelvis is contracted in all its dimensions, and its meters may be as much as 12·5 mm. less than the average, and this even ell-formed women of average height. The principal divergences, however, ound at the superior aperture, and affect the relation of the anteroposterior e transverse diameter. Thus the superior aperture may be elliptical in a transverse or an anteroposterior direction, the transverse diameter e former, and the anteroposterior in the latter, greatly exceeding the diameters; in other instances it is almost circular.

In the *fœtus*, and for several years after birth, the pelvis is small in portion to that of the adult, and the projection of the sacrovertebral angle marked. The characteristic differences between the male and female s are distinctly indicated as early as the fourth month of fœtal life.

Applied Anatomy.—There is arrest of development in the bones of the pelvis in cases troversion of the bladder; the anterior part of the pelvic girdle is deficient, the or rami of the pubic bones are imperfectly developed, and the symphysis is absent. pubic bones are separated to the extent of from two to four inches, the superior shortened and directed forwards, and the obturator foramina diminished in size, ved, and turned outwards. The iliac bones are straightened out more than normal. transverse curve of the sacrum is flattened out or even convex, and the vertical curve ightened.*

ctures of the pelvis are divided into those of the greater and those of the lesser Fractures of the greater pelvis vary in extent; a small portion of the crest may ken, or one of the spinous processes may be torn off, or the bone may be extensively inuted. This latter accident is the result of some crushing violence, and may be ociated with fracture of the lesser pelvis. These cases may be accompanied by y to the intestine or to the iliac vessels. A fracture of the lesser pelvis generally s through the superior ramus of the os pubis and the inferior ramus of the ischium, ses are the weakest parts of the bony ring, and may be caused either by crushing ce applied in an anteroposterior direction, when the fracture occurs from direct or by compression laterally, when the acetabula are pressed together and the bone way in the same place from indirect violence. Sometimes both sides of the pelvis ctured, and it is in these cases that the contained viscera are likely to be injured: rethra, the bladder, the rectum, the small intestines, the vagina, and even the uterus, e been lacerated by displaced fragments. Fractures of the acetabulum are occa- y met with: either a portion of the rim may be broken off, or a fracture may take through the bottom of the cavity, and the head of the femur be driven into the pelvic Separation of the Y-shaped cartilage at the bottom of the acetabulum may also in the young subject, splitting the bone into its three portions.

he coccyx is not infrequently displaced forwards to nearly a right angle with the m by a kick or by a fall backwards. The condition is attended with great pain in ing and on making any expiratory effort, such as coughing, defæcation, etc., because coccygei and Levatores ani which form the pelvic diaphragm are attached to this Such injuries often give rise to severe persistent pain, which is exceedingly table and difficult of cure. The condition is known as *coccygodynia*, and for its emoval of the coccyx has been practised.

pelvic bones often undergo important deformity in *rickets*, the effects of which in lt woman may seriously interfere with child-bearing. The deformity is due mainly weight of the trunk, which presses on the sacrovertebral angle and greatly increases that the anteroposterior diameter of the pelvis is diminished, and may measure as s 40 mm., the entrance into the pelvis becoming reniform. In other cases all the pelvic yield, and a general diminution in all the diameters of the pelvis results, the pelvic e becoming triangular or asymmetrical. If the pubic symphysis be forced forwards, ckety pelvis may even come to resemble closely the deformed pelvis of *osteomalacia*; s disease the weight of the trunk causes an increase in the sacrovertebral angle, and ing of the anteroposterior diameter of the superior aperture, and at the same time ssure of the heads of the femora on the acetabula causes these cavities, with the ent bone, to be pushed upwards and backwards, so that the oblique diameters of ris are also diminished, and the cavity of the pelvis assumes a triradiate shape, the symphysis pubis pushed forwards.

THE FEMUR

e femur (figs. 419 and 420), the longest and strongest bone in the skeleton, ndrical in the greater part of its extent. In the erect posture it is placed ely, being separated above from the bone of the opposite limb by an val which corresponds to the breadth of the pelvis, but inclines gradually

* Wood. Heath's *Dictionary of Practical Surgery*.

Digitized by Arya Samaj Foundation Chennai and eGangotri

downwards and medialwards, so as to bring the knee-joint near the gravity of the body. The degree of this inclination varies in different and is greater in the female than in the male, on account of the greater of the pelvis. The femur has a body and two ends.

The **upper end** of the femur (fig. 418) comprises a head, a neck, and a lesser trochanter.

The *head* forms rather more than a hemisphere; it articulates acetabulum of the hip-bone, and is directed upwards, medialwards little forwards. Its surface is smooth, except at an ovoid depression, *capitis femoris*, which is situated a little below and behind the centre of and gives attachment to the ligamentum teres of the hip-joint.

Fig. 418.—The upper extremity of the right femur. From behind and al

The *neck* of the femur is flattened anteroposteriorly; it connects th with the body, and forms with the latter an angle of about 125°. Th decreases during the period of growth, but after full growth has been a it does not usually undergo any change; in the female, in consequence greater width of the pelvis, it is less than in the male. In addition to pro upwards and medialwards from the body of the femur, the neck p somewhat forwards; the amount of this forward projection is ext variable, but on an average is from 12° to 14°.

The neck is contracted in the middle, and broader laterally than me The vertical diameter of the lateral half is increased by the obliquity lower edge, which slopes downwards to join the body at the level of the trochanter; the medial half is smaller, and of a more cylindrical shape. *anterior surface* of the neck is perforated by numerous foramina for v Along the upper part, and encroaching on the line of junction of this with the head is a shallow, rough groove, best marked in elderly subjects groove lodges the orbicular fibres of the capsule of the hip-joint. The p

running vertically downwards for about 5 cm. along the triangular surface between the lateral and intermediate ridges of the linea aspera; it gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus; as a rule, there is merely a slight thickening about the middle of the intertrochanteric crest, marking the attachment of the upper part of the Quadratus femoris.

The **body or shaft** of the femur, almost cylindrical in form, is a little broader above than in the centre, broadest and somewhat flattened from before backwards below. It is slightly arched, so as to be concave behind, where it is strengthened by a prominent longitudinal crest, the *linea aspera*. It has three borders and three surfaces. Of the borders, one, the linea aspera, is posterior, one is medial, and the other, lateral.

The *linea aspera* (fig. 420) is a longitudinal crest, on the middle third of the shaft; it has a medial and a lateral lip, and a narrow, rough, intermediate ridge. Three ridges, lateral, intermediate and medial, run upwards from the linea aspera. The lateral ridge is very rough, and ascends to the base of the greater trochanter; it is termed the *glutæal tuberosity*, and gives insertion to the tendon of the Glutæus maximus; its upper part is often elongated into a raised crest, on which a rounded tubercle, the *third trochanter*, is occasionally developed. The intermediate ridge or *pectineal line* is continued to the base of the lesser trochanter and gives insertion to the Pectineus. The medial ridge or *spiral line* is continuous with the intertrochanteric line. The lips of the linea aspera diverge below and are prolonged as two epicondylar ridges to form the sides of a triangular area named the *popliteal surface*. The lateral epicondylar ridge is the more prominent, and descends to the lateral condyle. The medial epicondylar ridge is indistinct above where it is crossed by the femoral artery; it ends below, at the medial epicondyle, in the *adductor tubercle*, which affords insertion to the tendon of the Adductor magnus. In about 80 per cent. of specimens a rounded tubercle is present on the lower part of the popliteal surface, just above the medial condyle; to this tubercle the upper part of the medial head of the Gastrocnemius is attached.*

Fig. 421.—The lower end of the right femur. Inferior aspect.

From the medial lip of the linea aspera and its prolongations above and below, the Vastus medialis arises; and from the lateral lip and its upward prolongation, the Vastus lateralis takes origin. The Adductor magnus is inserted into the linea aspera, and to its lateral prolongation above, and its medial prolongation below. Between the Vastus lateralis and the Adductor magnus the Glutæus maximus is inserted above, and the short head of the Adductor femoris takes origin below. Between the Adductor magnus and the Vastus medialis four muscles are inserted: the Iliacus and the Pectineus above, the Adductor brevis and the Adductor longus below. Near the middle

rmedius arises from its upper three-fourths, and from the upper part of its r one-fourth the Articularis genus takes origin. The *lateral surface* is ween the lateral border and the linea aspera; it is continuous above with lateral surface of the greater trochanter, below with that of the lateral ycle: the Vastus intermedius arises from its upper three-fourths. The *dial surface* is between the medial border and the linea aspera; it is continuous ve with the lower border of the neck, below with the medial side of the dial condyle; it is covered by the Vastus medialis.

The lower end of the femur (figs. 421, 422) is larger than the upper, and sists of two oblong eminences, known as the *condyles*; in front, these are but tly prominent, and are separated by a smooth shallow articular depression d the *patellar surface*; behind, they project considerably, and are separated deep notch, the *intercondyloid fossa*. The *lateral condyle* is the more pro nt anteriorly, and is the broader both in its anteroposterior and transverse meters. The *medial condyle* projects to a lower level than the lateral, when femur is held with its body perpendicular; when, however, the bone is s natural oblique position the lower surfaces of the two condyles lie in the horizontal plane. The condyles are not quite parallel with one another; long axis of the lateral is almost directly anteroposterior, but that of the l runs backwards and medialwards. Their opposed surfaces are small, and concave, and form the walls of the intercondyloid fossa; this fossa ted above by a ridge, the *intercondyloid line*, and below by the central of the posterior margin of the patellar surface. The posterior cruciate ment of the knee-joint is attached to the lower and front part of the medial of the fossa, and the anterior cruciate ligament to the upper and posterior of its lateral wall. Each condyle is surmounted by an elevation, the ndyle. The *medial epicondyle* is a large convex eminence to which the tibial teral ligament of the knee-joint is attached. At its upper part is the ctor tubercle, already referred to, and behind it is a rough impression which s origin to a large part of the medial head of the Gastrocnemius. The *lateral ndyle* (fig. 422), smaller and less prominent than the medial, gives attach- t to the fibular collateral ligament of the knee-joint. Directly below it is a ll depression from which a deep, oblique groove curves upwards and back- s to the posterior end of the condyle. This groove is separated from the ular surface of the condyle by a rounded across the anterior part of which a vertical, low groove descends from the depression. the recent state these grooves are covered cartilage. The Popliteus arises from the ression below the epicondyle; its tendon lies oblique groove when the knee is acutely and in the vertical groove when the knee tended. Above and behind the lateral epi- yle is an area for the origin of the lateral of the Gastrocnemius, above and medial to h the Plantaris arises.

FIG. 424.—A scheme showing the disposition of the principal cancellous lamellæ in the upper end of the femur.

The *articular surface* of the lower end of the r occupies the anterior, inferior, and erior surfaces of the condyles. Its front articulates with the patella, and is named *patellar surface*; it presents a median ve between two convexities, the lateral of h is broader, more prominent, and ascends er than the medial. The lower and erior parts of the articular surface con- te the *tibial surfaces* for articulation with rresponding condyles of the tibia and the l of the knee-joint. The tibial surfaces are separated from one another intercondyloid fossa, and from the patellar surface by two faint grooves extend obliquely across the condyles. The lateral groove is the better ed; it runs lateralwards and slightly forwards from the front part of the ondyloid fossa, and expands to form a triangular depression which rests the anterior portion of the lateral meniscus when the knee-joint is fully

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

extended. The medial groove is less distinct than the lateral, and ex
on the medial part of the condyle; it receives the anterior edge of the
meniscus when the knee-joint is extended. Where this groove ceases
the patellar surface is continued backwards on the medial condyle a
lunar area adjoining the anterior part of the intercondyloid fossa; this
area articulates with the medial vertical facet of the patella in forced
the knee-joint. The tibial surfaces of the condyles are convex from sid
and from before backwards. Each presents a double curve, its posterior
being an arc of a circle, its anterior, part of a cycloid.*

FIG. 425.—An oblique section through the upper end of the left femur showing the calcar femorale.

FIG. 426.—A plan of the ossificatio
femur. From five centres.

Structure.—The body of the femur is a cylinder of compact bone, hollo
a large medullary canal. The wall of the cylinder is thick in the middle
of the body, where the bone is narrowest and the medullary canal best
but above and below this the wall becomes thinner, while the medullary
gradually filled up by spongy substance, so that the upper and lower end
body, and the articular extremities more especially, consist of spongy sub
invested by a thin compact layer.

The cancelli in the ends of the femur are disposed along the lines of greates
sure and tension. In the upper end (figs. 423, 424) the chief lamellæ are
in the following manner. A series of bony planes at right angles to the
surface of the head converge to a central dense wedge; this wedge is

* A *cycloid* is a curve traced by a point in the circumference of a wheel when the

e body and transmit to the body forces applied to the upper end of the bone. e spongy substance of the neck is a thin vertical plate of bone, the *calcar* rale (fig. 425), which springs from the compact wall of the body in the region of linea aspera. Medially it is attached to the inner surface of the posterior wall e neck of the bone; laterally it continues the plane of the posterior wall of ck into the greater trochanter, where it shades off into the general spongy ance. It is thus situated in a plane anterior to the intertrochanteric crest to the base of the lesser trochanter.

n the lower end, the cancelli spring on all sides from the inner surface of the ler, and descend in a direction perpendicular to the articular surface, the ll being strongest and having a more accurately perpendicular course above ndyles. In addition to this, there are horizontal planes of cancellous tissue, at the spongy substance in this situation is mapped out into a series of cubical artments.

ssification (figs. 426, 427, 428).—The femur is ossified from five centres: one for the body, head, greater trochanter, lesser trochanter, and lower end

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Except the clavicle, it is the first of the long bones to show traces of os
Ossification begins in the middle of the body in the seventh week of fœtal
extends upwards and downwards. The secondary centres appear as
in the lower end, during the ninth month of fœtal life (from this centre the
and epicondyles are formed); in the head at the end of the first year; in the
trochanter during the fourth year; and in the lesser trochanter between
teenth and fourteenth years. The epiphyses, derived from the secondary
fuse independently with the body after puberty; the lesser trochanter
then the greater, then the head, and, lastly, the lower end which is
until the twentieth year.

Applied Anatomy.—The lower end of the femur is the only epiphysis in which
tion has commenced at the time of birth. The presence of this centre of ossifi
therefore, a proof, in a new-born child found dead, that the child has arrived at
period of uterogestation, and is always relied upon in medico-legal investigation
position of the epiphysial plate should be carefully noted. It is on a level
adductor tubercle, and the epiphysis does not, therefore, form the whole of the
covered portion of the lower end of the bone. It is essential to bear this point in
performing excision of the knee, since growth in length of the femur takes place
from the lower epiphysis, and any interference with the epiphysial cartilage in
child would involve such ultimate shortening of the limb, from want of growth
render the limb almost useless. Separation of the lower epiphysis may take place
the age of twenty, at which time it becomes completely joined to the body of the
but, as a matter of fact, few cases occur after the age of sixteen or seventeen.
physis of the head of the femur is the seat of origin, in a large number of cases,
culous disease of the hip-joint. In the majority of cases the disease begins in the
vascular and growing tissue at the end of the body in the neighbourhood of the
cartilage, and extends into the joint. The epiphysis for the head is entirely intra

Fractures of the femur are divided, like those of the other long bones, into fra
the upper end; of the body; and of the lower end. The fractures of the upper
be classified into (1) fracture of the neck; (2) fracture at the junction of the
the greater trochanter; (3) fracture of the greater trochanter; and (4) separation
epiphysis, either of the head or of the greater trochanter. The first of these, fra
the neck, is usually termed *intracapsular* fracture, but this is scarcely a correct
tion, as, owing to the attachment of the articular capsule, the fracture is partly
and partly without the capsule when the fracture occurs at the lower part of the
generally takes place in old people, principally women, and usually from a very
degree of indirect violence. Probably the main cause of its occurrence in old
the senile degenerative change which takes place in the bone. Merkel believes
mainly due to the absorption of the calcar femorale. As a rule the fragments
united by fibrous tissue, but frequently no union takes place, and the opposed
become smooth and eburnated.

Fractures at the junction of the neck with the greater trochanter are usually
extracapsular, but this designation is also incorrect, as the fracture is partly within
capsule, which is attached in front to the intertrochanteric line below the line of
These fractures are produced by direct violence to the greater trochanter, as from
laterally on the hip. From the manner in which the accident is caused the neck
bone is driven into the trochanter, where it may remain impacted or the trochanter
be split into two or more fragments, disimpaction resulting.

Fractures of the body may occur at any part, but the most usual situation is at
the centre of the bone. Fractures of the upper third of the body are almost always
result of indirect violence, while those of the lower third are the result, for the most
direct violence. Fractures of the body are generally oblique, but they may be transverse
longitudinal, or spiral. The transverse fracture occurs most frequently in children
fractures of the lower end of the femur include transverse fracture above the condyles
the most common; and this may be complicated by a vertical fracture between
condyles, constituting the T-shaped fracture. In these cases the popliteal artery
danger of being wounded. Oblique fracture separating either the medial or
condyle, and a longitudinal incomplete fracture between the condyles, may also
place.

When there is a possibility of a fracture of the femur resulting in shortening
bone, treatment should be carried out in the abducted position, so that the tilting
pelvis to counteract the abduction may produce lengthening. The replacement of fra
of the lower one-third is facilitated by flexing the knee and so relaxing the gastrocnemius
and the hamstrings.

The femur is exposed, with least injury to the vascular and nervous supply
muscles, through an incision in the line of the lateral intermuscular septum.

The femur and the other long bones of the leg are frequently the seat of
osteomyelitis in children. This is no doubt due to their greater exposure to
which is often the exciting cause of this disease. Necrosis of portions of the dia

ently ensue, especially in the region of the popliteal space and of the femur, and the se may continue for years, great trouble being experienced with discharging sinuses periodically close and reopen to allow of the exit of pieces of dead bone.

umours are not infrequently found growing from the femur: the most common being sarcoma, which may grow either from the periosteum or from the medullary within the interior of the bone, and exostosis, which commonly originates in the bourhood of the epiphysial cartilage of the lower end. The region of the lower ysial line is by far the commonest seat for all these tumours, and it should be noted he lower epiphysis has the longest period of active growth, and that these tumours y appear towards the end of the period of active growth of the bone.

The Tibia

he tibia (figs. 430, 431) is situated at the medial side of the leg, and, ding the femur, is the longest bone of the skeleton. It is prismoid in expanded above, where it enters into the formation of the knee-joint, cted in the lower one-third, and again enlarged, but to a lesser extent, . It has a body and two ends.

Fig. 429.—The upper surface of the right tibia.

he upper end of the tibia (fig. 429) is expanded into two eminences, the *l and lateral condyles*, the superior surfaces of which form the medial and l articular surfaces. The medial articular surface, oval in shape, is y concave from side to side, and from before backwards; the lateral, y circular, is concave from side to side, but slightly convex from before wards, especially at its posterior part where it is prolonged on to the erior surface for a short distance. The central portions of the medial and al articular surfaces articulate with the condyles of the femur, while their teral portions support the menisci of the knee-joint, which here intervene ween the tibia and the femoral condyles. Between the articular surfaces, nearer the posterior than the anterior part of the bone, is the *intercondyloid* nence (tibial spine), surmounted by two prominent tubercles, on the sides hich the articular surfaces are prolonged; in front of and behind the rcondyloid eminence are rough depressions, the *anterior and posterior rcondyloid fossæ*, for the attachment of the cruciate ligaments and the isci of the knee-joint. The anterior surfaces of the condyles are continuous one another, forming a large, triangular, somewhat flattened area; this area orated by foramina for vessels, and ends below in an oblong elevation, the sity of the tibia, which gives attachment to the ligamentum patellæ; a intervenes between the deep surface of the ligament and the part of the immediately above the tuberosity. The *medial condyle* is grooved eriorly, for the insertion of the tendon of the Semimembranosus; its medial ace, convex, rough and prominent, gives attachment to the posterior part the tibial collateral ligament of the knee-joint. The *lateral condyle* presents

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

posteriorly a flat, nearly circular articular facet directed downwards, wards, and lateralwards, for articulation with the head of the fibula. It surface is convex, rough and prominent in front: on it is an eminence, on a level with the articular facet for the fibula, for the attachment iliotibial tract or band of the fascia lata. Just below this eminence a the tendon of the Biceps femoris is inserted, and a small part of the digitorum longus takes origin.

The **body or shaft** of the tibia has three crests or margins, and three

The *anterior crest* or *shin*, the most prominent, begins above at the tu and ends below at the anterior margin of the medial malleolus. It is and prominent in its upper two-thirds, but smooth and rounded below; attachment to the deep fascia of the leg.

The *medial margin* is smooth and rounded above and below, b prominent in the centre; it begins at the posterior part of the medial and ends at the posterior border of the medial malleolus; its upper p attachment to the tibial collateral ligament of the knee-joint to the of about 5 cm., and insertion to some fibres of the Popliteus; from its one-third some fibres of the Soleus and Flexor digitorum longus take orig

The *interosseous crest* gives attachment to the crural interosseous me (fig. 434), and is most distinct in the middle one-third of the bone; it above in front of the fibular articular facet, and bifurcates below to form sides of a triangular rough depression, the *fibular notch*, for the attachment interosseous ligament connecting the tibia and fibula.

The *medial surface* is smooth and convex, and is broader above than Its upper one-third is covered by an aponeurosis derived from the tendo Sartorius, and by the tendons of the Gracilis and Semitendinosus; all th inserted into this part of the bone. The rest of the surface is subcutan

The *lateral surface* is narrower than the medial; on its upper two-th shallow groove for the origin of the Tibialis anterior; its lower one- smooth, convex, curves gradually forwards to the anterior aspect of th and is covered by the tendons of the Tibialis anterior, Extensor hallucis and Extensor digitorum longus, arranged in this order from the medial

At the upper part of the *posterior surface* (fig. 431) is a prominent the *popliteal line*, which descends obliquely from the fibular articul to the medial border, near the junction of the upper with the middle one- the fascia covering the Popliteus muscle is attached to this line, and p the Soleus, Flexor digitorum longus, and Tibialis posterior take origin Above the line is a triangular area, into the greater part of which the Po is inserted; immediately below the line is the orifice of the nutrient canal is large and directed obliquely downwards. The middle one-third posterior surface is divided into two areas by a vertical ridge which be the popliteal line and is usually well marked above, but indistinct below medial and broader area gives origin to the Flexor digitorum longus, the and narrower to a part of the Tibialis posterior. The lower part of the po surface is smooth and covered by the Tibialis posterior, Flexor dig longus, and Flexor hallucis longus.

The **lower end** of the tibia is prolonged downwards on its medial sid strong process, the *medial malleolus*. The *inferior articular surface* is lateral, and articulates with the talus. It is broader in front than b concave from before backwards, and near the middle is traversed in this di by a slight elevation. It is continuous with the articular surface on the side of the medial malleolus. The *anterior surface* is smooth and ro above, and covered by the tendons of the Extensor muscles; at its margin is a furrow for the attachment of the articular capsule of the ankle The lateral part of the *posterior surface* is traversed by a shallow groove, di obliquely downwards and medialwards, in which the tendon of the hallucis longus lies. On the *lateral surface* is a triangular rough depr the *fibular notch*, for the attachment of the interosseous ligament conne the tibia with the fibula; in the recent state, the lower border of this is occasionally covered with cartilage, and articulates with the fibula fibular notch is bounded by two prominent borders, continuous above w interosseous crest; their lower parts afford attachment to the anterior posterior ligaments of the lateral malleolus.

The *medial malleolus* is a strong pyramidal process, flattened fro side. Its *medial surface* is convex and subcutaneous; its *lateral or surface*, smooth and slightly concave, articulates with the talus; its *border* is rough, for the attachment of the anterior fibres of the deltoid of the ankle-joint: on its *posterior border* is a broad groove, the *malleo* directed obliquely downwards and medialwards, and occasionally do lodges the tendons of the Tibialis posterior and Flexor digitorum long *lower border* of the malleolus is marked posteriorly by a depressio attachment of the deltoid ligament of the ankle-joint.

Fig. 432.—A plan of the ossification of the tibia. From three centres.

Fig. 433.—The epiphysial l right tibia and fibula i adult. Anterior aspect.

The lines of attachment of the capsules are in blue.

Structure.—The structure of the tibia is like that of the other long bon compact wall of the body is thickest at the junction of the middle with t one-third of the bone.

Ossification.—The tibia is ossified from three centres (figs. 432, 433) the body and one for either end. Ossification begins in the middle of t about the seventh week of fœtal life. The centre for the upper end appe or shortly after birth, and from it a thin tongue-shaped process extends d in front, to form the tuberosity (fig. 433); the centre for the lower en in the second year. The lower end joins the body about the eighteen the upper about the twentieth year. Two additional centres occasion one for the tongue-shaped process which forms the tuberosity, and on medial malleolus.

The Fibula

The **fibula** (figs. 430, 431) is placed on the lateral side of the tibia connected to it above and below. In proportion to its length it is slender of all the long bones. Its upper end articulates with th of the lateral condyle of the tibia, below the level of the knee-joint. T inclines a little forwards so that its lower end or lateral malleolus is on

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

erior to that of the upper end; it projects below the tibia, and forms the
ral part of the ankle-joint.

The upper end or head of the fibula is of an irregular quadrate form, and
a flattened articular surface, directed upwards, forwards, and medialwards,
rticulation with the lateral condyle of the tibia. On its lateral side is
ick and rough prominence, continued behind into a pointed eminence,
per or *styloid process*, which projects upwards from the posterior part of the
d. The upper and lateral parts of this prominence give attachment to the
ion of the Biceps femoris and to the fibular collateral ligament of the knee-
t, the ligament dividing the tendon into two parts. The remaining part
he head is rough, for the attachment of muscles and ligaments; in front
tubercle for the origin of the highest fibres of the Peronæus longus, and a
ce for the attachment of the anterior ligament of the head of the bone;
nd, is another tubercle for the attachment of the posterior ligament of the
d of the fibula, and a few fibres of the Soleus.

FIG. 434.—A transverse section through the right tibia and fibula, showing the attachment of the crural interosseous membrane.

The body or shaft of the fibula has four borders—anterolateral, anteromedial, rolateral, and posteromedial; and four surfaces—anterior, posterior, rial, and lateral.

The *anterolateral border* begins above in front of the head, runs vertically rwards to a little below the middle of the bone, and then curving lateral-ds, divides to form the sides of a triangular subcutaneous surface which is nued on to the lateral malleolus. This border gives attachment to the or fibular intermuscular septum which separates the extensor muscles e front of the leg from the Peronæus longus and Peronæus brevis on the ral side

The *anteromedial border*, or *interosseous crest*, is on the medial side of the rolateral border; it runs close to and nearly parallel with the upper one-l of this border, but diverges from its lower two-thirds. It begins above below the head of the bone, and is sometimes quite indistinct for about m.; it ends at the apex of a rough triangular surface which is situated e the articular facet of the lateral malleolus. It serves for the attachment e crural interosseous membrane (fig. 434) which separates the extensor es in front from the flexor muscles behind.

The *posterolateral border* is prominent; it begins above at the styloid ess of the head and ends below in the posterior border of the lateral eolus. It is directed lateralwards above, backwards in the middle of its se, backwards and a little medialwards below, and gives attachment to osterior fibular intermuscular septum which separates the Peronæi on the l side from the Soleus and Flexor hallucis longus behind.

The *posteromedial border*, sometimes called the *oblique line*, begins above e medial side of the head and ends by joining the interosseous crest at lower part of the bone; it is well marked and prominent in its upper and dle parts. It gives attachment to an aponeurosis which separates the tis posterior from the Soleus and Flexor hallucis longus.

The *anterior surface* is the interval between the anterolateral and medial borders. It is narrow and flat in the upper one-third of its broader and grooved longitudinally in its lower one-third; it serves origin of the Extensor digitorum longus, Extensor hallucis longus, and Pe tertius.

The *posterior surface* is between the posterolateral and poster borders; it is continuous below with the triangular area above the surface of the lateral malleolus, and is directed backwards above, and wards below. Its upper one-third is rough for the origin of the Sole lower part, triangular in shape, is connected to the tibia by a strong inter ligament; the intervening part gives origin to a portion of the Flexor longus. Near the middle of this surface is the orifice of the nutrien which is directed downwards.

FIG. 435.—The lower end of the right fibula. Medial aspect.

FIG. 436.—A plan of the of the fibula. From three

The *medial surface*, between the anteromedial and posteromedial b gives origin to part of the Tibialis posterior.

The *lateral surface*, between the anterolateral and posterolateral b is broad and often deeply grooved. It is directed lateralwards in its two-thirds, and backwards in its lower one-third, where it is continuo the posterior border of the lateral malleolus. The upper part of this gives origin to the Peronæi longus et brevis; the lower part is covered tendons of these muscles.

The **lower end** of the fibula, or *lateral malleolus*, is of a pyramidal and somewhat flattened from side to side; it descends to a lower level the medial malleolus. The *lateral surface* is convex, and continuous w triangular, subcutaneous surface on the lateral side of the body of the The *medial surface* (fig. 435) presents in front a smooth triangular s convex from above downwards, which articulates with the lateral side talus. Behind and distal to the articular surface is a rough depression attachment of the posterior talofibular ligament. The *anterior border* is and rough, and marked below by a depression for the attachment of the talofibular ligament. The *posterior border* is broad, and presents a s

Digitized by Arya Samaj Foundation Chennai and eGangotri

cal groove which is traversed by the tendons of the Peronæi longus et is. The *summit* is rounded, and gives attachment to the calcaneofibular ment.

Ossification.—The fibula is ossified from three centres (fig. 436): one for the and one for either end. Ossification begins in the body about the eighth of fœtal life, in the lower end during the second year, and in the upper about fourth year. The lower epiphysis, the first to ossify, unites with the body at the twentieth year; the upper about the twenty-fifth year.

Applied Anatomy.—In fractures of the bones of the leg, both bones are generally red, but either bone may be broken separately, the fibula more frequently than the When fracture occurs from indirect force, the break in the tibia is at the junction e middle with the lower one-third, or weakest part of the bone, while the fracture of bula is usually at a rather higher level. These fractures present great variety, both ards their direction and condition. They may be oblique, transverse, longitudinal, ral. When oblique, they are for the most part the result of indirect violence, and rection of the fracture is downwards, forwards, and medialwards in many cases, but e downwards and lateralwards, or downwards and backwards. When transverse, ture is often at the upper part of the bone, and is the result of direct violence. piral fracture of the tibia generally starts as a vertical fissure, involving the ankle- and is associated with fracture of the fibula higher up. It is the result of torsion, rsting of the body while the foot is fixed.

ctures of the tibia alone are almost always the result of direct violence, except the malleolus is broken off by twists of the foot. Fractures of the fibula alone may from indirect or direct force, those of the lower end being usually the result of the t, and those higher up being caused by a direct blow on the part; the common neal nerve, where it winds round the neck of the fibula, may be injured at the time e fracture, or subsequently by ill-applied splints.

he tibia is the bone which is most commonly and most extensively distorted in ts. It bends at the junction of the middle and lower third, its weakest part, and ers a curve forwards with generally some lateral displacement.

he tibia is more often the seat of acute infective necrosis than any other bone in the s, and with the formation of the sequestrum a large amount of new bony material is n out by the periosteum. The sequence of events in this disease can be very closely ved in the case of the tibia, and it is not uncommon to find a patient from whom hole diaphysis of the tibia has been removed, going about with a new bone entirely eriosteal formation. Chronic bone abscess is more frequently met with in the llous tissue of the head or lower end of the tibia than in any other bone in the . These abscesses are very chronic, and in most cases the result of tuberculous s, although they are sometimes due to the organisms of suppuration or even the us typhosus.

The Patella

e patella (figs. 437, 438), the largest of the sesamoid bones, is situated s of the knee-joint in the tendon of the Quadriceps femoris. It is d triangular, and has an anterior and a posterior surface, three borders, n apex.

Fig. 437.—The right patella. Anterior aspect.

Fig. 438.—The right patella. Posterior aspect.

The *anterior surface* rvex, perforated by ures for the passage rient vessels, and ed by numerous longitudinal striæ. separated from the by a bursa and is ed, in the recent by an expansion the tendon of the riceps femoris; this ion is continuous with the super- fibres of the ligamentum patellæ. The *posterior surface* presents above oth, oval, articular area, divided into two facets by a vertical ridge; ridge corresponds to the groove on the patellar surface of the femur, and facets to the medial and lateral parts of the same surface; the lateral is the broader and deeper. Below the articular surface is a rough,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

convex, non-articular area, the lower part of which gives attachme ligamentum patellæ.

The *base* or *superior border* is thick, and sloped from behind, do and forwards: it gives attachment, except near its posterior margin portion of the Quadriceps femoris which is derived from the Rectus fe Vastus intermedius. The *medial and lateral borders* are thinner and below: they give attachment to those portions of the Quadriceps which are derived from the Vasti medialis et lateralis. Near the of the superior and lateral borders is a small shallow circular depre which a part of the tendon of the Vastus lateralis is inserted.

The *apex* is pointed, and gives attachment to the ligamentum pate

Structure.—The patella consists of a nearly uniform dense spongy covered by a thin compact lamina. The cancelli immediately beneath th surface are arranged parallel with it. In the rest of the bone they rad the articular surface towards the other parts of the bone.

Ossification.—The patella is ossified from a single centre, which usual its appearance in the second or third year, but may be delayed until the si Ossification is completed about the age of puberty.

Applied Anatomy.—Fractures of the patella are of frequent occurrence. most often produced by muscular action—that is to say, by violent contracti Quadriceps femoris while the limb is in a position of semiflexion, so that th snapped across the condyles of the femur and the fracture is transverse. Fract patella is also produced by direct violence, such as falls on the knee, and here th is usually stellate and the bone comminuted. In fractures by muscular action th and lateral retinacular fibres of the articular capsule of the knee-joint are separation of the fragments takes place. When the fracture is caused by direct these retinacular fibres are not torn, and the fragments remain in contact. In by muscular action the fibrous expansion of the Quadriceps femoris which passe front of the patella to the ligamentum patellæ is torn from the front of the lower and falls as a veil over the fracture-surface of the upper fragment. Owing condition just described, (2) the displacement of the fragments, and (3) the di maintaining the latter in apposition, union takes place by fibrous tissue w subsequently stretch, producing wide separation of the fragments and perma ness. Really satisfactory results after this fracture are generally only to be ob opening the joint, removing the overhanging aponeurosis, and wiring the together.

If the fracture involve only the lower and non-articular part of the bone, anatomical possibility for such to take place without injury to the synovial str without involving the cavity of the knee-joint.

THE SKELETON OF THE FOOT

The skeleton of the foot (figs. 439, 440) consists of three segment tarsal bones, the metatarsal bones, and the phalanges or bones of the di

The Tarsal Bones (Ossa Tarsi)

The **tarsal bones** are seven in number: viz. the talus, calcaneus, na first, second, and third cuneiforms, and the cuboid.

The Talus (figs. 441 to 444)

The **talus** (astragalus), the second largest of the tarsal bones, the tibia and rests on the calcaneus; it articulates on either side corresponding malleolus, and in front with the navicular bone. It of a head, neck, body, and trochlea.

The **head** of the talus is directed forwards and medialwards. Its *or navicular surface* is oval and convex, with its long axis running do and medialwards; it articulates with the concavity of the navicula

lus projects as a rough, triangular eminence, named the *lateral process*; the lateral talocalcaneal ligament is attached. In front of the articular ce for the lateral malleolus is a rough impression for the anterior talo-ar ligament, while below and behind it is a groove in which a part of posterior talofibular ligament is implanted.

n the *plantar surface* of the body (fig. 442) is the *posterior calcaneal surface*, h is large in size and oval in form for articulation with the dorsal surface e calcaneus. It is limited in front by the sulcus tali and is deeply concave e direction of its long axis, which runs forwards and lateralwards at an e of about 45° with the median plane.*

The *posterior surface* of the body is small, and projects backwards as the rior *process*; it is traversed in a direction downwards and medialwards sulcus for the tendon of the Flexor hallucis longus (fig. 441). On either of this sulcus is a tubercle. That on the lateral side is the more pro-nt and gives attachment to the main part of the posterior talofibular ent; it is sometimes detached from the rest of the bone, and is then n as the *os trigonum*. To the smaller medial tubercle the medial calcaneal ligament is attached.

The Calcaneus (figs. 445 to 448)

The calcaneus (os calcis) is the largest of the tarsal bones. It is situated at lower and posterior part of the foot, and forms a strong lever for the cles of the calf. It is irregularly cuboidal in shape, having its long axis ted forwards and lateralwards.

445.—The left calcaneus. Dorsal aspect.

Fig. 446.—The left calcaneus. Plantar aspect.

The *dorsal surface* (fig. 445) consists of a posterior non-articular and an rior articular part. The former varies in length in different individuals, onvex from side to side, concave from before backwards, and supports a

* R. B. S. Sewell (*Journal of Anatomy and Physiology*, vol. xxxviii.) pointed out that in about per cent. of bones a small triangular facet, continuous with the posterior calcaneal facet, is ent at the junction of the lateral surface of the body with the posterior wall of the sulcus tali.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

mass of fat placed in front of the tendo calcaneus. In front of this a *posterior articular surface*, a large, usually somewhat oval-shaped fac looks upwards and forwards; it is convex from behind forwards, and a with the posterior calcaneal facet on the plantar surface of the tal bounded anteriorly by a deep depression which is continued back medialwards in the form of a groove, the *sulcus calcanei*; in the a foot this sulcus lies below the sulcus tali, and the two sulci form a t sinus tarsi, already referred to (p. 338). In front and medial to th is an elongated facet, concave from behind forwards, and with diameter directed forwards and lateralwards. This facet is frequently into two parts: of these, the posterior and larger is termed the *middle surface*; it is supported on a projecting process of bone, the *sustenac* and articulates with the middle calcaneal facet on the plantar surfa talus; the anterior and lesser, termed the *anterior articular surface*, on the front part of the body, and articulates with the anterior calcan on the plantar surface of the talus. The dorsal surface, anterior and to the facets, is rough for the attachment of ligaments and for the the Extensor digitorum brevis.

FIG. 447.—The left calcaneus. Lateral aspect.

The *plantar surface* (fig. 446) is uneven, wider behind than in fro convex from side to side; it is bounded posteriorly by the lower part calcaneal tuberosity, which presents a medial and a lateral process; the *process*, small, prominent, and rounded, gives origin to part of the Ab digiti quinti; the *medial process*, broader and larger, gives attachme its prominent medial margin, to the Abductor hallucis, and in front plantar aponeurosis and the Flexor digitorum brevis; from the dep between the processes a part of the Abductor digiti quinti takes origin rough surface in front of the processes gives attachment to the long p ligament and the lateral head of the Quadratus plantæ; to a prominent tu near the anterior part of this surface and to a transverse groove in front tubercle, the plantar calcaneocuboid ligament is attached.

The *lateral surface* (fig. 447) is broad behind, and narrow in front, fl almost subcutaneous; near its centre is a small tubercle, for the attac of the calcaneofibular ligament. Below and in front of this tubercle is a the *trochlear process* (peronæal tubercle), which is often indistinctly m It gives attachment to the inferior peronæal retinaculum, and separates grooves; the superior groove transmits the tendon of the Peronæus lo the inferior, that of the Peronæus longus.

The *medial surface* (fig. 448) is directed obliquely downwards and for and is deeply concave; above the anterior part of the concavity is a sh projection, the *sustentaculum tali*. The dorsal surface of the sustentaculu is concave, and articulates with the middle calcaneal articular surface talus; its plantar surface is grooved for the tendon of the Flexor h

is; the narrow, medial surface is overlaid by the tendon of the Flexor orum longus, and is grooved near its upper margin for the attachment part of the deltoid ligament of the ankle-joint. The anterior margin of the ntaculum tali gives attachment to the plantar calcaneonavicular ligament. he *anterior extremity* or articular surface for the cuboid bone is of a somewhat gular form. It is concave from above downwards and lateralwards, and ex in a direction at right angles to this. Its medial border gives attachment e plantar calcaneonavicular ligament.

FIG. 448.—The left calcaneus. Medial aspect.

The *posterior extremity* or *calcaneal tuberosity* is prominent, convex, wider n than above, and divisible into three areas. The lowest of these areas is h, and covered by the fatty and fibrous tissue of the heel; the middle, rough, gives insertion to the tendo calcaneus and Plantaris; while the est is smooth, and is covered by a bursa which intervenes between this part e tuberosity and the tendo calcaneus. The plantar surface of this tuberosity ays the medial and lateral processes already described (p. 340).

THE NAVICULAR BONE (OS NAVICULARE PEDIS)

The navicular bone (fig. 449) is situated at the medial side of the tarsus, en the talus behind and the cuneiform bones in front.

The *anterior surface* is convex from side to side, and subdivided by two s into three facets, for articulation with the three cuneiform bones. The

FIG. 449.—The left navicular bone. A. Anterior aspect. B. Posterior aspect.

erior surface, oval and concave, articulates with the anterior surface of the d of the talus. The *dorsal surface* is convex from side to side, and rough

for the attachment of ligaments. The *plantar surface*, irregularly displays on its lateral part a downward projection of varying size, the *process*, to which a portion of the plantar calcaneonavicular ligament is The *medial surface* consists of a rounded *tuberosity*, the lower part gives insertion to a large part of the tendon of the Tibialis posterior. the tuberosity and the plantar process is a groove for the lodgment of the tendon of the Tibialis posterior. The *lateral surface* is rough and for the attachment of ligaments, and frequently presents a facet for ar with the cuboid bone.

The Cuneiform Bones (Ossa Cuneiformia)

The **cuneiform bones** (fig. 439), three wedge-shaped bones, artic the navicular bone behind and with the first, second, and third metatar in front; the first cuneiform bone is the largest, and the second the In the articulated foot the posterior surfaces of the three cuneiform be a slight concavity for the navicular, but the anterior portions of the third project in front of the anterior surface of the second, and form a deep recess in which the base of the second metatarsal bone is lodged.

The **first cuneiform bone** (os cuneiforme primum) (fig. 450) is at the medial side of the foot, between the navicular bone behind and of the first metatarsal bone in front.

Fig. 450.—The first left cuneiform bone. A. Medial aspect. B. Lateral as

The *medial surface* is subcutaneous, broad and quadrilateral; at its plantar angle is a smooth oval impression, into which a part of the ten the Tibialis anterior is inserted. The *lateral surface* is concave; al superior and posterior borders is a narrow L-shaped articular surface, the limb and posterior part of the horizontal limb of which articulate w second cuneiform bone, while the anterior part of the horizontal limb art with the second metatarsal bone; the facet for the second metatarsal occasionally separated by a groove from that for the second cuneiform The rest of this surface is rough for the attachment of ligaments and the tendon of the Peronæus longus. The *anterior surface*, large and shaped, articulates with the base of the first metatarsal bone. The *surface*, triangular and concave, articulates with the medial facet on the surface of the navicular bone. The *plantar surface* forms the base wedge; at its posterior part is a tuberosity for the insertion of part tendon of the Tibialis posterior; in front of this a part of the ten the Tibialis anterior is inserted. The *dorsal surface* is the thin end wedge, and is directed upwards and lateralwards; it is rough f attachment of ligaments.

The **second cuneiform bone** (os cuneiforme secundum) (fig. 451), regular wedge-like form, is situated between the first and third cu bones.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The *anterior surface*, triangular in form, articulates with the base of the and metatarsal bone. The *posterior surface*, also triangular, articulates the intermediate facet on the anterior surface of the navicular bone. the *medial surface* is an L-shaped facet, running along the superior and erior borders, for articulation with the first cuneiform bone; the rest the surface is rough for the attachment of ligaments. The *lateral surface* ents posteriorly a vertical facet for articulation with the third cuneiform The *dorsal surface* or base of the wedge is quadrilateral and rough

FIG. 451.—The second left cuneiform bone.

A. Anteromedial aspect. B. Posterolateral aspect.

the attachment of ligaments. The *plantar surface*, sharp and tuberculated, also rough for the attachment of ligaments, and for the insertion of a slip the tendon of the Tibialis posterior.

The third **cuneiform bone** (os cuneiforme tertium) (fig. 452) has its base ted upwards; it is placed between the second cuneiform and cuboid es.

The *anterior surface*, triangular in form, articulates with the base of the third tarsal bone. The *posterior surface* articulates with the lateral facet on the erior surface of the navicular bone, and is rough below for the attachment ligamentous fibres. The *medial surface* presents an anterior and a posterior ular facet: the anterior, sometimes divided into two, articulates with the eral side of the base of the second metatarsal bone; the posterior skirts the erior border, and articulates with the second cuneiform bone; the inter- ing rough area gives attachment to an interosseous ligament. The *lateral* ce also presents two articular facets; the anterior one, situated at the

FIG. 452.—The third left cuneiform bone. A. Anterolateral aspect. B. Posteromedial aspect.

erior angle of the bone, is small and semi-oval in shape, and articulates with medial side of the base of the fourth metatarsal bone; the posterior and er one is triangular or oval, and articulates with the cuboid bone; the rvening, rough, non-articular area serves for the attachment of an inter- eous ligament. The *dorsal surface* or base of the wedge is of an oblong ro, its posterolateral angle being prolonged backwards. The *plantar surface* narrow and rounded, and serves for the attachment of ligaments and parts the tendons of the Tibialis posterior and Flexor hallucis brevis.

The Cuboid Bone (Os Cuboideum)

The **cuboid bone** (fig. 453) is placed on the lateral side of the foot of the calcaneus, and behind the fourth and fifth metatarsal bones.

Fig. 453.—The left cuboid bone. A. Anteromedial aspect. B. Posterolateral

The *dorsal surface*, directed upwards and lateralwards, is rough attachment of ligaments. The *plantar surface* is crossed in front by groove, the *peronæal sulcus*, which runs obliquely forwards and medi it lodges the tendon of the Peronæus longus, and is bounded behind prominent ridge, to which the long plantar ligament is attached. T ends laterally in the *tuberosity*, the lateral part of which carries an oval on this facet the sesamoid bone or cartilage which is frequently found tendon of the Peronæus longus glides. Behind the peronæal sulcus th is rough, for the attachment of the plantar calcaneocuboid ligament, a few of the Flexor hallucis brevis, and a fasciculus from the tendon of the posterior. On the *lateral surface* is a deep notch which marks the com ment of the peronæal sulcus. The *posterior surface* is smooth, triangul concavoconvex, for articulation with the anterior surface of the calcaneu plantar, medial angle projects backwards as a process which underl supports the anterior end of the calcaneus. The *anterior surface* is divi a vertical ridge into two facets ; the medial, quadrilateral in form, arti with the fourth metatarsal bone ; the lateral, triangular, with the fifth *medial surface* is irregularly quadrilateral, and at its middle and dors is a smooth oval facet, for articulation with the third cuneiform bone; this a small facet for articulation with the navicular bone is frequently pr the rest of this surface is rough for the attachment of interosseous ligame

The Metatarsal Bones (Ossa Metatarsi)

The **metatarsal bones**, five in number, are enumerated from the side of the foot.

The Common Characteristics of the Metatarsal Bones

Each metatarsal bone has a body, a base or proximal end, and a h distal end.

The **body** of each bone is prismoid in form ; it tapers gradually from th to the head, and is slightly convex longitudinally on its dorsal surface.

The **base** articulates with the tarsus, and with the contiguous meta bones.

The **head** articulates with the proximal phalanx by a convex arti surface which extends farther backwards on the plantar than on the d surface ; the plantar extension ends on either side on the summit of a s

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ular eminence. The sides of the head are flattened and on each is a ession surmounted by a tubercle for the attachment of one of the collateral ments of the metatarsophalangeal joint.

The Characteristics of the Individual Metatarsal Bones

The first metatarsal bone (fig. 454) is the shortest and thickest of the tarsal bones. The *body* is strong, and of well-marked prismoid form. *base* has, as a rule, no articular facets on its sides, but there is occasionally on the lateral side for articulation with the second metatarsal bone. Its nal articular surface, of large size and kidney-shaped, articulates with the cuneiform bone; its circumference is grooved, for the tarsometatarsal ents, and medially gives insertion to a part of the tendon of the Tibialis tor; its plantar angle presents a rough, oval prominence for the insertion e tendon of the Peronæus longus. The *head* is large; on its plantar ce is a median elevation separating two grooved facets on which sesamoid s glide.

54.—The first left metatarsal bone.

Fig. 455.—The second left metatarsal bone.

The second metatarsal bone (fig. 455) is the longest of the metatarsal s. On its wedge-shaped *base* are four articular facets: one on its proximal ce, of a triangular form, for articulation with the second cuneiform bone; at the upper part of its medial surface, for articulation with the first iform bone; and two on its lateral surface, an upper and lower, separated rough non-articular interval. Each of these lateral articular surfaces is ded by a vertical ridge; the two anterior facets articulate with the third tarsal bone; the two posterior (sometimes continuous) with the third iform bone. A fifth facet is occasionally present for articulation with the metatarsal bone; it is oval in shape, and is situated on the medial side e base, distal to the facet for the first cuneiform bone.

The third metatarsal bone (fig. 456) has a triangular *base* which articu- proximally with the third cuneiform bone; medially it articulates by two s with the second metatarsal bone; and laterally, by a single facet situated e dorsal angle, with the fourth metatarsal bone.

with the cuboid bone; on its lateral side a single facet, for the fifth me bone; on its medial side a facet divided by a ridge into an anterior po the third metatarsal bone, and a p portion for the third cuneiform bone.

Fig. 458.—The fifth left metatarsal bone.

The **fifth metatarsal bone** (fig recognised by a rough eminence, th *sity*, on the lateral side of its base *base* articulates proximally, by a tri obliquely cut surface, with the cuboi and medially, with the fourth me bone. On the medial part of its surface is inserted the tendon Peronæus tertius, and on the dorsal of the tuberosity that of the Peronæus A strong band of the plantar apo connects the projecting part of the tu with the lateral process of the tube the calcaneus. The plantar surface base is grooved for the tendon of the tor digiti quinti, and gives origin Flexor digiti quinti brevis.

The Phalanges of the Foot (Phal Digitorum Pedis)

The **phalanges** of the foot co in number and general arrangeme those of the hand; there are two in the great toe, and three in each of th toes. They are, however, much smaller, and their bodies, especially the bones of the first row, are compressed from side to side.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

he phalanges of the **first row** closely resemble those of the hand. The of each is compressed from side to side, convex above, concave below. ase is concave for articulation with the head of the corresponding meta- bone, and on the *head* is a trochlear surface for articulation with the phalanx.

he phalanges of the **second row** are remarkably small and short, but broader than those of the first row.

he **ungual phalanges** resemble those of the fingers; but they are smaller, re flattened from above downwards; each presents a broad base for lation with the corresponding bone of the second row, and an expanded extremity for the support of the nail and the end of the toe.

Ossification of the Bones of the Foot (fig. 459)

he **tarsal bones** are each ossified from a single centre, excepting the calcaneus has an epiphysis for its tuberosity. The centres make their appearance as

Fig. 459.—A plan of the ossification of the bones of the foot.

s: in the calcaneus, at the sixth month of fœtal life; in the talus, about the h month; in the cuboid, at the ninth month; in the third cuneiform, during st year; in the first cuneiform, during the third year; in the second cuneiform navicular, during the fourth year. The epiphysis for the tuberosity of the neus begins to ossify between the sixth and tenth years, and unites with the of the bone soon after puberty. The lateral tubercle of the posterior process

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the talus is sometimes ossified from an independent centre, and ma separate from the rest of the bone, when it is named the *os trigonum*.

The **metatarsal bones** are each ossified from two centres: a primary for the body, and a secondary or epiphysial centre for the base or proximal e first, and for the head or distal end of each of the other four.* Ossifica in the middle of the body about the eighth or ninth week of fœtal life. The for the base of the first metatarsal appears about the third year; those heads of the other metatarsals between the third and fourth years; all the bodies between the seventeenth and twentieth years. An epiphy quently present on the tuberosity of the base of the fifth metatarsal bone (fi

The **phalanges** are each ossified from two centres: a primary one for and an epiphysis for the base. The primary centres for the ungual appear about the eighth week of fœtal life; those for the first phalanges the twelfth and sixteenth weeks, and those for the second phalanges sixteenth week (that for the second phalanx of the fifth toe does not usua until after birth). The epiphysial centres appear between the third years, and unite with the bodies about the seventeenth or eighteenth year

Comparison of the Bones of the Hand and Foot

The hand and foot are constructed on somewhat similar principles, sisting of a proximal part, the carpus or tarsus, an intermediate portion,

Fig. 460.—The skeleton of the left foot. Medial aspect.

Fig. 461.—The skeleton of the left foot. Lateral aspect.

carpus or metatarsus, and a distal portion, the phalanges. The proxi consists of a series of more or less cubical bones which allow a slight a gliding on one another and are chiefly concerned in distributing forces tra to or from the bones of the arm or leg. The intermediate part is made up o

* As in the first metacarpal bone (see footnote, page 306), so in the first metatarsal often a second epiphysis for the head.

† C. Thurstan Holland, *Journal of Anatomy*, vol. lv., 1921.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ble long bones which assist the carpus or tarsus in distributing forces and give greater breadth for the reception of such forces. The separation of the dual bones from one another allows of the attachments of the interosseous les and protects the dorsipalmar and dorsiplantar vascular anastomoses. distal portion is the most movable, and its separate elements enjoy a varied of movements, the chief of which are flexion and extension.

The functions of the hand and foot are, however, very different, and the general arity between them is greatly modified to meet these requirements. Thus the forms a firm basis of support for the body in the erect posture, and is therefore solidly built, and its component parts are less movable on each other than of the hand. In the case of the phalanges the difference is readily noticeable; of the foot are smaller and their movements more limited than those of the

Very much more marked is the difference between the metacarpal bone of umb and the metatarsal bone of the great toe. The metacarpal bone of the b is constructed to permit of great mobility; it is directed at an acute angle that of the index finger, and is capable of a considerable range of movement articulation with the carpus. The metatarsal bone of the great toe assists in orting the weight of the body, is constructed with great solidity, lies parallel the other metatarsals, and has a very limited degree of mobility. The carpus ll in proportion to the rest of the hand, is placed in line with the forearm, and a transverse arch, the concavity of which constitutes a bed for the flexor s. The tarsus forms a considerable part of the foot, and is placed at right s to the leg, a position which is almost peculiar to man, and has relation to his posture. In order to allow of their supporting the weight of the body with least expenditure of material the tarsus and metatarsus are constructed in es of arches (figs. 460, 461), the disposition of which will be considered the articulations of the foot have been described.

plied Anatomy.—Considering the injuries to which the foot is subjected, it is sur- g how seldom the tarsal bones are fractured. This is no doubt due to the fact that rsus is composed of a number of bones, articulated by a considerable extent of e, and joined together by very strong ligaments which serve to break the force of ce applied to this part of the body. When fracture does occur, these bones being sed for the most part of a soft cancellous structure, covered only by a thin shell of act tissue, are often extensively comminuted, especially as most of the fractures are ced by direct violence; and, as there is only a very scanty amount of soft parts over ces, the fractures are very often compound, and amputation is often necessary.

hen fracture occurs in the anterior group of tarsal bones, it is almost invariably the t of direct violence; but fractures of the posterior group—that is, of the calcaneus lus—are usually produced by falls from a height on to the feet.

club-foot (talipes), especially in congenital cases, the bones of the tarsus become d in shape and size, and displaced from their proper positions. This is principally e in congenital talipes equinovarus, in which the head of the talus becomes twisted ophied, and a similar condition may be present in the other bones, more especially vicular.

e tarsal bones are peculiarly liable to become the seat of tuberculous caries following atively trivial injuries. Caries of the calcaneus or talus may remain limited to e bone for a long period, but when one of the other bones is affected, the remainder ily become involved, since the disease spreads through the large and complicated al stratum which is more or less common to these bones.

mputation of the foot is often required either for injury or disease. The principal ations are as follows: (1) Syme's: amputation at the ankle-joint by a heel-flap, emoval of the malleoli and sometimes a thin slice from the lower end of the tibia. rgoff's: amputation of the whole of the tarsal bones (except the posterior part of lcaneus), and a thin slice from the tibia and fibula including the two malleoli. The surface of the calcaneus is then turned up and united to the cut surface of the tibia. bastragalar: amputation of the foot below the talus through the joint between it the calcaneus.

the bones of the tarsus occasionally require removal individually. This is especially ne with the talus for tuberculous disease limited to that bone; or the talus may e excision in cases of subastragalar dislocation, or in cases of inveterate talipes. boid has been removed for the same reason.

e metatarsal bones, and especially that of the great toe, are frequently diseased, in tuberculous subjects or in patients with perforating ulcer of the foot.

THE SESAMOID BONES *

The **sesamoid bones** are small more or less rounded masses of bone in certain tendons and usually related to joint-surfaces. Their probably are to modify pressure, to diminish friction, and occasionally the direction of the pull of a muscle. That they are not developed certain physical requirements in the adult is evidenced by the fact are present as cartilaginous nodules in the fœtus, and in greater than in the adult. They must be regarded as integral parts of the phylogenetically inherited.† Physical necessities probably come into selecting and in regulating the degree of development of the origi laginous nodules.

Sesamoid bones are invested by the fibrous tissue of the tendon on the surfaces in contact with the parts over which they glide, w present smooth articular facets.

In the upper extremity the sesamoid bones of the joints are fo on the palmar surface of the hand. Two, of which the medial is th are present at the metacarpophalangeal joint of the thumb; one is fo present in the corresponding joint of the index finger, and one (or the same joint of the little finger. Sesamoid bones are found occasi the metacarpophalangeal joints of the middle and ring fingers, at t phalangeal joint of the thumb, and at the distal interphalangeal joi index finger.

In the lower extremity the largest sesamoid bone of the joints is th developed in the tendon of the Quadriceps femoris. On the plant of the foot, two, of which the medial is the larger, are always prese metatarsophalangeal joint of the great toe; one sometimes at th tarsophalangeal joints of the second and fifth toes, one occasionall corresponding joints of the third and fourth toes, and one at the interp joint of the great toe.

Sesamoid bones apart from joints are seldom found in the tendo upper limb; one is sometimes seen in the tendon of the Biceps brachi the radial tuberosity. They are, however, present in several of the of the lower limb—viz. one in the tendon of the Peronæus longus, glides on the cuboid bone; one, appearing late in life, in the tendon of th anterior, opposite the smooth facet of the first cuneiform bone; o tendon of the Tibialis posterior, opposite the medial side of the hea talus; one in the lateral head of the Gastrocnemius, behind the latera of the femur; and one in the tendon of the Psoas major, where it gli the os pubis. Sesamoid bones are found occasionally in the tendo wind round the medial and lateral malleoli, and one is sometimes p the tendon of the Glutæus maximus where it passes over the greater tro of the femur.

SYNDESMOLOGY

bones of the skeleton are connected to one another at different parts their surfaces, and such connexions are termed *joints* or *articulations*. the joints are *immovable*, as in the articulations of the cranium, the ed margins of the bones are nearly in contact, being separated merely thin layer of fibrous membrane, named the *sutural ligament*; in certain ns at the base of the skull this fibrous membrane is replaced by a layer rtilage. Where *slight movement* combined with great strength is required, pposed osseous surfaces are united by tough and elastic *fibrocartilages*, as e joints between the vertebral bodies, and in the interpubic articulation. e *freely movable* joints the opposed surfaces are completely separated one another; the parts of the bones forming the articulations are expanded reater convenience of mutual connexion, and are covered with *hyaline lar cartilage*, while the joints are enveloped by *articular capsules*, and are lly strengthened by strong fibrous bands called *ligaments*.

In long bones the ends are the parts which form the articulations; they omewhat enlarged, and consist of spongy substance with a thin coating mpact substance. In the flat bones the articulations usually take place e edges, and in the short bones at various parts of their surfaces. The of compact bone which forms the joint surface, and to which the articular lage is attached, is called the *articular lamella*; its lacunæ are large, but ntains no Haversian canals or canaliculi. The vessels of the spongy nce approach the articular lamella but do not perforate it; this lamella equently denser and firmer than ordinary bone.

The **articular cartilage** which covers the articular surfaces of bones, the **fibrocartilage** which enters into the structure of some of the joints, described in the section on Histology (pp. 14 to 17).

The **ligaments** are composed mainly of parallel or closely interlaced bundles *hite fibrous tissue*, and present a silvery appearance. They are pliant flexible, so as to allow perfect freedom of movement, but strong, tough, and tensible, so as not to yield readily to applied force. Some ligaments consist ly of *yellow elastic tissue*, as the ligamenta flava which connect together laminæ of adjacent vertebræ, and the ligamentum nuchæ in the lower nals. In these cases the elasticity of the ligament is intended to act as stitute for muscular power.

The **articular capsules** form complete envelopes for the freely movable s. Each capsule consists of two strata—an external (stratum fibrosum) posed of white fibrous tissue, and an internal (stratum synoviale) which metimes described separately as the synovial membrane of the joint.

The *stratum fibrosum* is attached to the circumferences of the articular of the bones entering into the joint, and thus entirely surrounds the ulation.

The *stratum synoviale* invests the inner surface of the stratum fibrosum, ollected over any tendons passing through the joint cavity, and ceases the margins of the articular cartilages. It is composed of a thin, delicate,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

connective tissue, and is covered on its free surface with a layer of end
In some joints it is thrown into folds which pass across the cavity
knee-joint; in others there are flattened folds, subdivided at their
into fringe-like processes which contain convoluted vessels. Th
generally project near the margin of the cartilage, and lie flat upon
The endothelium of the stratum synoviale secretes a small quantity
lubricating fluid, termed *synovia*.

Closely related in structure and function to the synovial stratu
articular capsule, and therefore conveniently described in this sec
the vaginæ mucosæ of tendons and the bursæ mucosæ.

Vaginæ mucosæ (mucous sheaths) serve to facilitate the gliding of
in fibro-osseous canals, e.g. the tendons of the flexor and extensor
of the fingers and toes as they pass through canals in or near the
foot. Each sheath has the form of an elongated closed sac which
wall of the canal, and is reflected upon the surface of the enclosed
tendons.

Bursæ mucosæ are interposed between surfaces which glide upon ea
They consist of closed sacs containing a minute quantity of clear vis
and may be grouped, according to their situations, under the head
cutaneous, *submuscular*, *subfascial*, and *subtendinous*.

A CLASSIFICATION OF THE JOINTS

Joints are divided into three classes: *synarthroses* or immovable
arthroses or slightly movable, and *diarthroses* or freely movable joints.

1. Synarthroses. (Immovable Articulations)

Synarthroses are articulations in which the surfaces of the b
fastened together by intervening connective tissue or hyaline cartil
in which there is no appreciable motion, as in the joints between the
the cranium. There are three varieties of synarthrosis: sutura, go
and synchondrosis.

Sutura is an articulation met with only in the skull, where the
of the bones articulate with one another (fig. 462). The margins of th
are not in direct contact, being separated by a thin layer of fibrous
continuous externally with the pericranium, internally with the dura m

Fig. 462.—A section through the sagittal suture.

Fig. 463.—A section through the sphenoidal synchondrosis of an

When the bony margins are connected by a series of interlocking
like processes, the articulation is named *sutura serrata*, as in the
suture. When the articulation is formed by one bone overlapping
as in the suture between the temporal and parietal bones, it is termed
squamosa; where there is simple apposition of contiguous rough surf
between the palatine processes of the maxillæ, or between the horizont
of the palatine bones, it is named *sutura palatina*.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Gomphosis is articulation by the insertion of a conical process into a socket; seen in the articulations of the roots of the teeth with the alveoli of the dible and maxillæ.

Synchondrosis.—Where the connecting medium is cartilage the joint is d a synchondrosis (fig. 463); this is a temporary form of joint, for the lage is ultimately converted into bone. Such joints are found between epiphyses and bodies of long bones, between the occipital and sphenoidal s at and for some years after birth, and between the petrous portions of emporal bones and the jugular process of the occipital bone.

2. Amphiarthroses. (Slightly Movable Articulations)

In these articulations the contiguous bony surfaces are either united by an osseous ligament, as in the inferior tibiofibular articulation, or are covered articular cartilage and connected by broad flattened discs of fibrocartilage, more or less complex structure, as in the articulations between the bodies e vertebræ. The first form is termed a **syndesmosis**, the second a **physis** (fig. 464).

3. Diarthroses. (Freely Movable Articulations)

This class includes the majority of the joints. In a diarthrodial joint contiguous bony surfaces are covered with articular cartilage, and con- ed by an articular capsule and ligaments (fig. 465).

Fig. 464.—A section through a symphysis. Diagrammatic.

465.—A section through a simple rodial joint. Diagrammatic.

Fig. 466.—A section through a diarthrodial joint with an articular disc. Diagrammatic.

oint may be completely divided by an *articular disc* (fig. 466), or incom- by *menisci* (fig. 521); the periphery of such structures is continuous with ibrous stratum of the articular capsule while their free surfaces are covered the synovial stratum.

Diarthrodial joints are classified according to the kind of motion permitted them. There are two varieties in which the movement is uni-axial; that

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is to say, all movements take place around one axis. In one, the or *hinge-joint*, this axis is, practically speaking, transverse; in the *articulatio trochoidea* or *pivot-joint*, it is longitudinal. There are two where the movement is bi-axial; these are the *articulatio ellipsoidea* or *joint* and the *articulatio sellaris* or *saddle-joint*. There is one form movement is poly-axial, the *articulatio sphæroidea* or *enarthrosis* (*ball-* *joint*); and finally there is the *arthrodia* or *gliding joint*.

Ginglymus or hinge-joint.—In this form the articular surfaces are to each other in such a manner as to permit motion only in one pla articular surfaces are connected together by strong collateral ligamen form their chief bond of union. The best examples of ginglymus interphalangeal joints, and the joint between the humerus and ulna.

Trochoid articulation or pivot-joint.—Where the movement is to rotation, the joint is formed by a pivot turning within a ring, or a ring on a pivot, the ring being formed partly of bone, partly of ligam the proximal radio-ulnar articulation, the ring is formed by the radi of the ulna and the annular ligament; here, the head of the radius within the ring. In the articulation of the dens of the epistropheus atlas, the ring is formed in front by the anterior arch, and behind transverse ligament, of the atlas; here, the ring rotates round the dens.

Condyloid articulation.—In this form of joint, an ovoid convex surface, or condyle, is received into an elliptical concavity in such a as to permit of flexion, extension, adduction, abduction, and circum but no axial rotation. The radiocarpal joint is an example of this articulation.

Saddle-articulation.—In this variety the opposing surfaces are cally concavoconvex, and the movements are the same as in the p form. The best example of the saddle-articulation is the carpom joint of the thumb.

Enarthrosis is a joint in which the distal bone is capable of motion an indefinite number of axes, which have one common centre. It is by the reception of a globular head into a cup-like cavity, hence th 'ball-and-socket.' Examples of this form of articulation are found hip- and shoulder-joints.

Arthrodia is a joint which admits of only gliding movement; it is by the apposition of plane, or nearly plane, surfaces, the amount of m such joints being limited by the ligaments or osseous processes sur the articulations. It is the form present in the joints between the processes of the vertebræ, and in most of the carpal and tarsal joints.

The Kinds of Movement permitted in Joints

The movements permitted in joints may be divided into four kinds: and angular movements, circumduction, and rotation. Frequently these or less combined in the various joints, so as to produce an infinite vari it is seldom that only one kind of motion is found in any particular joint.

Gliding movement is the simplest kind of motion that can take place in one surface gliding over another without any angular or rotatory movem is common to all movable joints; but in some, as in most of the articulation carpus and tarsus, it is the only motion permitted. This movement is not to plane surfaces, but may take place between any two contiguous surf whatever form.

Angular movement occurs only between the long bones, and by it th between the two bones is increased or diminished. It may take place: (1) f and backwards, constituting flexion and extension; or (2) towards and f median plane of the body, or, in the case of the fingers or toes, from the line of the hand or foot, constituting adduction and abduction. The ginglymoid or hinge-joints admit of flexion and extension only. Abduction adduction, combined with flexion and extension, are met with in the more joints.

Circumduction is that form of motion which takes place between the h bone and its articular cavity, when the bone is made to circumscribe a conical

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

base of the cone is described by the distal end of the bone, the apex is in the ular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is a form of movement in which a bone moves round a longitudinal : the axis of rotation may lie in a separate bone, as in the case of the pivot ed by the dens of the epistropheus around which the atlas turns; or a bone rotate around its own longitudinal axis, as in the rotation of the humerus he shoulder-joint; or the axis of rotation may not be quite parallel to the long of the bone, as in the movement of the radius on the ulna during pronation supination of the hand, where it is represented by a line connecting the centre he head of the radius with the centre of the head of the ulna.

Applied Anatomy.—W. W. Keen points out how important it is 'that the surgeon uld remember the ligamentous action of muscles in making passive motion—for ance, at the wrist after Colles's fracture. If the fingers be extended, the wrist can be d to a right angle. If, however, they be first flexed as in "making a fist," flexion he wrist is quickly limited to from forty to fifty degrees in different persons, and is painful beyond that point. Hence passive motion here should be made with the ers extended. In the leg, when flexing the hip, the knee should be flexed.'

THE MANDIBULAR JOINT

The bony parts entering into the formation of the mandibular (temporo-ndibular) joint are: above, the articular tubercle and the anterior portion the mandibular fossa of the temporal bone; below, the condyle of the ndible. An articular disc divides the joint into an upper and a lower cavity. ligaments of the joint are the following:

The articular capsule.	Sphenomandibular.
Temporomandibular.	Stylomandibular.

Fig. 467.—The left mandibular joint. Lateral aspect.

The articular capsule is a thin, loose envelope, attached, above, to the mference of the mandibular fossa and the articular tubercle; below, the neck of the mandible. The synovial stratum of the articular capsule ntinued over the upper and lower surfaces of the articular disc.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **temporomandibular ligament** (external lateral ligament) consists of two short, narrow fasciculi, one in front of the other, attached to the lateral surface of the zygomatic process of the temporal bone and to the tubercle on its lower border; to the lateral surface and posterior border of the neck of the mandible. It is shorter above than below, and its fibres are directed obliquely downwards and backwards.

Fig. 468.—The left mandibular joint. Medial aspect.

The **sphenomandibular ligament** (fig. 468) is a thin band which is attached above to the spina angularis of the sphenoidal bone, becoming broader as it descends, is fixed to the lingula of the mandibular foramen. Its lateral surface is in relation above, with the Pterygoideus externus; lower down it is separated from the neck of the condyle by the internal maxillary vessels; still lower the inferior alveolar artery and nerve and a lobule of parotid gland lie between it and the ramus of the mandible. Its medial surface is in relation with the Pterygoideus internus.

The **articular disc** (fig. 469) is a thin, oval plate, placed between the condyle of the mandible and the mandibular fossa; it divides the joint into two cavities. Its upper surface is concavoconvex from before backwards to accommodate itself to the form of the mandibular fossa and the articular tubercle. Its under surface, in contact with the condyle, is concave. Its circumference is connected to the articular capsule, and in front to the tendon of the Pterygoideus externus. It is thicker at its periphery, especially behind, than at its centre, where it is sometimes perforated.

Fig. 469.—A sagittal section through the mandibular joint.

The **stylomandibular ligament** (fig. 468) is a specialised band of the fascia colli (p. 448), which stretches from the apical part of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible between the Masseter and Pterygoideus internus. It separates the parotid from the submaxillary gland, and from its deep surface fibres of the Styloglossus take origin. Although classed among the ligaments of the mandibular joint, it can only be considered as accessory to it.

* J. Cameron (*Journal of Anatomy and Physiology*, vol. xlix.) points out that the crura of this ligament 'enters the inner extremity of the Glaserian fissure and whilst doing so is attached to the spine of the sphenoid by its inner edge.' He suggests that the attachment to the spina angularis of the sphenoidal bone is purely adventitious, and that the morphological attachment is in reality to the lips of the fissure and also within the tympanic cavity, where a considerable proportion of the fibres are directly continuous with the fibres of the membrana tympani. This intratympanic portion is usually described as the anterior ligament of the malleus. It forms a prominent band in a seven months' fœtus, and at this time appears to be independent of the sphenoidal bone.

The *nerves* of the mandibular joint are derived from the auriculotemporal and masseteric branches of the mandibular nerve, the *arteries* from the superficial temporal branch of the external carotid artery, and from the internal maxillary artery.

Movements.—The mandible may be depressed and elevated, or carried forwards and backwards; a slight amount of side-to-side movement is also permitted. When the mouth is opened the body of the mandible is depressed, and the condyles and articular discs are pulled forwards on to the articular tubercles; in shutting the mouth the reverse action takes place. When the mandible is carried horizontally forwards, as in protruding the lower incisor teeth in front of the upper, the discs and the condyles glide forwards on the mandibular fossæ and articular tubercles. The grinding or chewing movement is produced by one condyle, with its disc, gliding alternately forwards and backwards, while the other condyle moves simultaneously in the opposite directions; at the same time the condyle undergoes a vertical rotation on the disc. One condyle advances and rotates, while the other recedes and rotates.

Muscles producing the movements:

Depression.—Digastrici, Mylohyoidei, Geniohyoidei and Pterygoidei externi.
Elevation.—Masseteres, Temporales and Pterygoidei interni.
Protrusion.—Pterygoidei interni et externi (both sides).
Retraction.—Temporales (posterior fibres).
Lateral movement.—Pterygoidei interni et externi (one side).

Applied Anatomy.—The mandible can be dislocated only in one direction—viz. forwards. When the mouth is open, the condyle is situated on the articular tubercle, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forwards into the infratemporal fossa. The displacement may be unilateral or bilateral. Reduction is accomplished by depressing the jaw with the thumbs placed on the last molar teeth, and at the same time elevating the chin. The downward pressure overcomes the spasm of the Masseter, Temporalis, and Pterygoideus internus, and elevation of the chin throws the condyle backwards; the above-mentioned muscles then draw the condyle back into its normal position.

In close relation to the condyle of the mandible are the external acoustic meatus and the tympanic cavity; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to them. On the other hand inflammation of the tympanic cavity may involve the articulation and cause obstruction, thus leading to ankylosis of the joint.

THE ARTICULATIONS OF THE VERTEBRAL COLUMN

The vertebræ from the third cervical to the first sacral inclusive are articulated to one another by: (1) a series of amphiarthrodial joints between the vertebral bodies; and (2) a series of diarthrodial joints between the vertebral arches.

I. The Articulations of the Vertebral Bodies

The amphiarthrodial articulations between the bodies of the vertebra allow only slight movement between adjoining bones, but when this slight movement takes place in a considerable length of the vertebral column, the total range of movement is great. The vertebral bodies are united by anterior and posterior longitudinal ligaments, and by intervertebral fibrocartilages.

The anterior longitudinal ligament (fig. 470) is a strong band of fibres, which extends along the anterior surfaces of the bodies of the vertebræ. It is broader below than above, thicker and narrower in the thoracic than in the cervical and lumbar regions, and somewhat thicker and narrower opposite the bodies of the vertebræ than opposite the intervertebral fibrocartilages. It is attached above, to the pharyngeal tubercle of the occipital bone, and since it extends to the anterior tubercle of the atlas, then to the front of the body of the epistropheus, and is continued down as far as the upper

part of the front of the sacrum. It consists of dense longitudinal fibre are intimately adherent to the intervertebral fibrocartilages and the pr margins of the vertebræ, but not to the middle parts of the vertebral bo the latter situation the ligament is thick and fills up the concavitie anterior surfaces, and makes the front of the vertebral column mo It is composed of several layers of fibres, of which the most superficial longest and extend between four or five vertebræ. The intermedia extend between two or three vertebræ, while the deepest reach from one to the next. At the sides of the bodies the ligament consists of a fe fibres which connect adjacent vertebræ.

The **posterior longitudinal ligament** (figs. 470, 471) is situated the vertebral canal on the posterior surfaces of the bodies of the v Above, it is attached to the body of the epistropheus, and is thence co

FIG. 470.—A median sagittal section through a portion of the lumbar region the vertebral column.

downwards to the sacrum; its upper end is intimately connected wi membrana tectoria which appears to be a continuation of it. It is b above than below, and thicker in the thoracic than in the cervical and l regions. In the situation of the intervertebral fibrocartilages and con margins of the vertebræ, where the ligament is more intimately adheren broad, and in the thoracic and lumbar regions presents a series of den with intervening concave margins; but it is narrow and thick over the c of the bodies, from which it is separated by the basivertebral veins. ligament is composed of smooth, shining fibres, denser and more co than those of the anterior ligament, and consists of superficial layers occ the interval between three or four vertebræ, and deeper layers which c between adjacent vertebræ.

The **intervertebral fibrocartilages** (figs. 470, 471) are interposed be the adjacent surfaces of the bodies of the vertebræ, from the epistro to the sacrum, and form the chief bonds of connexion between the vert Their shape corresponds with that of the bodies between which they are p Their thickness varies in different regions of the column, and in different of the same column; they are thicker in front than behind in the co

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

lumbar regions, and thus contribute to the anterior convexities of these s of the column; while they are of nearly uniform thickness in the thoracic on, the anterior concavity this part of the column almost entirely due to shape of the vertebral es. They are adherent, by surfaces, to thin layers of line cartilage which cover upper and under surfaces he bodies of the vertebræ; e lower cervical vertebræ, over, small joints with ular capsules are occa- ally present between the r surfaces of the bodies the margins of the fibro- lages on either side. The vertebral fibrocartilages closely connected to the or and posterior longi- al ligaments; in the acic region they are ed laterally, by means of interarticular ligaments, the heads of those ribs ch articulate with two ebræ. The interverte- fibrocartilages constitute ut one-fourth of the length he vertebral column, ex- ive of the first two verte- ; but this amount is not ally distributed between various bones, the cervical lumbar portions having, in proportion to their length, a much greater ont than the thoracic region, with the result that these parts possess ter pliancy and freedom of movement.

Fig. 471.—The posterior longitudinal ligament of the vertebræ, in the lumbar region.

ructure of the intervertebral fibrocartilages.—Each is composed, at its circumfer- of laminæ of fibrous tissue and fibrocartilage, forming the *annulus fibrosus*; and, centre, of a soft, pulpy, highly elastic substance, of a yellowish colour, which pro- considerably above the surrounding level when the disc is divided horizontally. pulpy substance (*nucleus pulposus*), especially well developed in the lumbar region, ains the remains of the notochord. The laminæ are arranged concentrically; the rmost consist of ordinary fibrous tissue, the others of white fibrocartilage. The inæ are not quite vertical in their direction, those near the circumference being ed outwards and closely approximated; while those nearest the centre curve in the osite direction, and are somewhat more widely separated. The fibres composing laminæ are directed, for the most part, obliquely from above downwards, the fibres jacent laminæ passing in opposite directions and varying in every layer: so that bres of one layer are directed across those of another, like the limbs of the letter X. laminar arrangement exists in about the outer half of each fibrocartilage. The substance presents no such arrangement, and consists of a fine fibrous matrix, aining angular cells united to form a reticular structure.

plied Anatomy.—When an aneurysm presses on the vertebral column, the vertebral s are often deeply eroded by it, while the intervertebral fibrocartilages remain . The fibrocartilages are the first to be destroyed, however, in tuberculosis of ertebral column, where, as not infrequently happens, the disease begins in a fibro- ge, and spreads thence to the bodies of the two adjoining vertebræ.

2. The Articulations of the Vertebral Arches

The joints between the articular processes of the vertebræ belo arthrodial variety and are enveloped by articular capsules; the lamin and transverse processes are connected by the following ligaments:

Ligamenta flava. Ligamentum nuchæ.
Supraspinal. Interspinal.
Intertransverse.

The **articular capsules** are thin and loose, and are attached to th of the articular processes of adjacent vertebræ; they are longer a in the cervical than in the thoracic and lumbar regions.

The **ligamenta flava** (figs. 470, 472) connect the laminæ of adjacent and are best seen from the interior of the vertebral canal. Their att

Fig. 472.—The ligamenta flava of the lumbar region. Anterior aspect.

extend from the articular capsules to the regions where the laminæ fuse the spinous processes; here their posterior margins come into contact to a certain extent united, small intervals being left for the passage of The ligamenta flava consist of yellow elastic tissue, the fibres of which perpendicular in direction, are attached to the anterior surface of the above, some distance from its inferior margin, and to the posterior and upper margin of the lamina below. The ligaments are thin, bu and long in the cervical region; they are thicker in the thoracic reg thickest in the lumbar region. Their elasticity helps to preserve the posture, and to assist the vertebral column in resuming it after flexion.

The **supraspinal ligament** (fig. 470) is a strong fibrous cord, which co together the apices of the spinous processes from the seventh cervical to the sacrum; fibrocartilage is developed in the ligament at its p attachment to the tips of the spinous processes. It is thicker and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the lumbar than in the thoracic region, and intimately blended in both
ations with the neighbouring fascia. The most superficial fibres of this
ment extend over three or four vertebræ; those more deeply seated pass
een two or three vertebræ; while the deepest connect the spinous processes
eighbouring vertebræ. Between the spinous processes it is continuous
the interspinal ligaments. Between the spinous process of the seventh
ical vertebra and the external occipital protuberance its place is taken by
ligamentum nuchæ.

The **ligamentum nuchæ** is a fibrous membrane, which, in the neck, is
ologous with the supraspinal ligament of the thoracic and lumbar vertebræ.
xtends from the external protuberance and median nuchal line of the
cipital bone to the spinous process of the seventh cervical vertebra. From
nterior border a fibrous lamina is given off, which is attached to the posterior
rcle of the atlas, and to the spinous processes of the cervical vertebræ, and
s a septum between the muscles of the two sides of the neck. In man it is
representative of an important elastic ligament, which, in some of the
r animals, serves to sustain the weight of the head.

The **interspinal ligaments** (fig. 470), thin and membranous, connect
ining spinous processes, and their attachments extend from the root to
pex of each process. They meet the ligamenta flava in front and the
spinal ligament behind. They are narrow and elongated in the thoracic
n; broader, thicker, and quadrilateral in form in the lumbar region; and
slightly developed in the neck.

The **intertransverse ligaments** are interposed between the transverse
esses. In the cervical region they consist of a few irregular, scattered
s; in the thoracic region they are rounded cords intimately connected
the deep muscles of the back; in the lumbar region they are thin and
branous.

3. The Sacrococcygeal Symphysis

This articulation is an amphiarthrodial joint, between the apex of the
rum and the base of the coccyx, the bones being united by anterior,
erior and lateral sacrococcygeal ligaments, and by a disc of fibrocartilage.

The anterior **sacrococcygeal ligament** (fig. 501) consists of a few irregular
s, which descend from the anterior surface of the sacrum to the front of the
yx, blending with the periosteum.

The posterior **sacrococcygeal ligament** is a flat band, which arises from
margin of the lower orifice of the sacral canal, and descends to be inserted
the posterior surface of the coccyx. This ligament completes the lower
of the sacral canal, and is divisible into a short *deep* and a longer *super-*
part.

A lateral **sacrococcygeal ligament** exists on either side and connects
transverse process of the coccyx to the inferior lateral angle of the sacrum;
mpletes the foramen for the fifth sacral nerve.

A thin disc of **fibrocartilage** is interposed between the contiguous surfaces
he sacrum and coccyx; it is somewhat thicker in front and behind than
he sides. Occasionally the coccyx is freely movable on the sacrum; in
cases an articular capsule lined with a synovial stratum is present.

The different segments of the coccyx are connected together by the
nsion downwards of the anterior and posterior sacrococcygeal ligaments,
annular discs of fibrocartilage being interposed between the segments.
the adult male, all the pieces become ossified together at a comparatively
y period; but in the female, this does not commonly occur until a later
od of life. At a more advanced age the joint between the sacrum and
yx is obliterated.

ackward and forward movements take place between the sacrum and
yx; their extent increases during pregnancy.

Movements.—The movements permitted in the vertebral column are: flexion,
ension, lateral movement, circumduction, and rotation.

In *flexion*, or movement forwards, the anterior longitudinal ligament is relaxed
the anterior parts of the intervertebral fibrocartilages are compressed; while
posterior longitudinal ligament, the ligamenta flava, and the interspinal and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

supraspinal ligaments are stretched, as well as the posterior fibres of the vertebral fibrocartilages. The interspaces between the laminæ are widened, the inferior articular processes glide upwards upon the superior articular processes of the subjacent vertebræ. Flexion is the most extensive of all the movements of the vertebral column, and is freest in the lumbar region.

In *extension*, or movement backwards, an exactly opposite disposition of the parts takes place. This movement is limited by the anterior longitudinal ligament and by the approximation of the spinous processes. It is freest in the cervical region.

In *lateral movements*, the sides of the intervertebral fibrocartilages are compressed, the extent of motion being limited by the resistance offered by the supraspinal ligaments. Lateral movements may take place in any part of the column, but are freest in the cervical and lumbar regions.

Circumduction is very limited, and is merely a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral fibrocartilages, which, although only slight between any two vertebræ, allows of a considerable extent of movement when it takes place in the whole length of the column, the front of the upper part of the column being turned to one or other side. This movement, which is to a slight extent in the cervical region, is freer in the upper part of the cervical region, and absent in the lumbar region.

The extent and variety of the movements are influenced by the shape and direction of the articular surfaces. In the *cervical* region the upward inclination of the superior articular surfaces allows of free flexion and extension. Extension can be carried farther than flexion; at the upper end of the region it is limited by the locking of the posterior edges of the superior atlantal facets in the condyloid fossæ of the occipital bone; at the lower end it is limited by a mechanism in which the inferior articular processes of the seventh cervical vertebra slip into a space behind and below the superior articular processes of the first thoracic. Flexion is arrested just beyond the point where the cervical convexity is straightened, and movement is checked by the apposition of the projecting lower lips of the bodies of the vertebræ with the shelving surfaces on the bodies of the subjacent vertebræ. Lateral flexion and rotation are free in the cervical region, and are always combined, the upward and medial inclinations of the superior articular surfaces limiting rotatory movement during lateral flexion. In the *thoracic* region, notably in the upper part, all the movements are limited in order to reduce interference with respiration to a minimum. The almost complete absence of an upward inclination of the superior articular surfaces prohibits any marked flexion, while extension is checked by the contact of the inferior articular margins with the laminæ and the contact of the spinous processes with one another. Rotation is free in the thoracic region: the superior articular processes are segments of a cylinder whose axis is in the mid-ventral line of the vertebral bodies. The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum. In the *lumbar* region flexion and extension are free. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebræ, and on this account a considerable amount of lateral flexion is permitted. For the same reason a slight amount of rotation can be carried out, but this is so soon checked by the interlocking of the articular surfaces that it is negligible.

Muscles producing the movements.—The vertebral column may be moved either by (*a*) muscles attached to it and acting directly on it, or by (*b*) muscles attached to other bones and acting indirectly on the column.

a. Muscles acting *directly* on the vertebral column.

Flexion.—Longus colli, Scaleni, Quadratus lumborum, Psoas major, Psoas minor.

Extension.—Interspinales, Multifidus, Spinales, Semispinales dorsi et cervicis, Iliocostalis cervicis, Longissimi dorsi et cervicis and Splenius cervicis.

Lateral flexion.—Intertransversarii, Multifidus, Iliocostalis cervicis, Longissimi cervicis, Splenius cervicis, Levatores costarum, Longus colli, Scaleni, Quadratus lumborum and Psoas major.

Rotation.—Rotatores, Multifidus, Splenius cervicis, Semispinales dorsi et cervicis, Levatores costarum and Longus colli.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

b. Muscles acting *indirectly* on the vertebral column.

Flexion.—Sternocleidomastoideus, Longus capitis and the abdominal muscles.

Extension.—Splenius capitis, Semispinalis capitis, Iliocostales lumborum et dorsi, and Longissimi dorsi et capitis.

Lateral flexion and rotation.—Sternocleidomastoideus, Obliqui abdominis, Iliocostales lumborum et dorsi, and Longissimi dorsi et capitis.

4. The Articulation of the Atlas with the Epistropheus

The articulation of the atlas with the epistropheus is of a complicated ure and comprises three joints. There is a pivot-joint between the dens he epistropheus and the ring formed by the anterior arch and the transverse

Fig. 473.—The anterior atlanto-occipital membrane.

ment of the atlas (fig. 475), and a pair of arthrodial or gliding joints between articular surfaces of the two bones. The bones are connected by two cular capsules and by the transverse ligament of the atlas.

The articular capsules are thin and loose, and surround the joints between articular surfaces. Each is strengthened at its posterior and medial part an *accessory ligament*, which is attached below to the body of the epistro- us near the base of the dens, and above to the lateral mass of the atlas near transverse ligament.

In front, the two vertebræ are connected by a continuation of the anterior gitudinal ligament (fig. 473). In this position it is a strong membrane, d, above, to the lower border of the anterior arch of the atlas, and below, to front of the body of the epistropheus. It is strengthened in the middle by a rounded cord, which connects the tubercle on the anterior arch of the to the body of the epistropheus.

Behind, the atlas and epistropheus are joined by a broad, thin membrane 473) attached, above, to the lower border of the posterior arch of the atlas, ow, to the upper edges of the laminæ of the epistropheus; it is in series h the ligamenta flava.

basilar part of the occipital bone between the ligamentum apicis de the membrana tectoria; the crus inferius is attached to the posterior of the body of the epistropheus; hence the whole ligament is na *ligamentum cruciatum atlantis.* The transverse ligament divides the ri atlas into two unequal parts: of these, the posterior and larger surro medulla spinalis and its membranes and the spinal parts of the accessory the anterior and smaller contains the dens. The neck of the dens is co where it is embraced posteriorly by the transverse ligament, so that this suffices to retain the process in position after all the others have been di

The joint-cavity between the dens and the transverse ligament continuous with those of the atlanto-occipital articulations.

Movements.—This articulation with its three joints allows the rotatio atlas (and, with it, the skull) upon the epistropheus, the extent of rotati limited by the alar ligaments (p. 367).

The opposed articular surfaces of the atlas and epistropheus are not cally curved; both are convex in their long axes. When, therefore, th facet glides forwards on the lower it also descends; the fibres of the capsule are relaxed in a vertical direction, and will then permit of mo in an anteroposterior direction. By this means a shorter capsule suffi the strength of the joint is materially increased.

Muscles producing the movements.—The principal muscles by which movements are produced are the Sternocleidomastoideus and Semispinalis of one side, acting with the Longus capitis, Splenius, Longissimus capitis capitis posterior major, and Obliquus capitis inferior of the other side.

THE ARTICULATIONS OF THE VERTEBRAL COLUMN WITH THE CRA

The ligaments connecting the vertebral column with the cranium divided into two sets; those uniting the atlas with the occipital bo those connecting the epistropheus with the occipital bone.

1. The Articulation of the Atlas with the Occipital Bon

The articulation between the atlas and the occipital bone consists of of condyloid joints. The ligaments connecting the bones are:

Two articular capsules.	Anterior and posterior atlanto-occipital membranes.

The **articular capsules** surround the condyles of the occipital bo the superior articular processes of the atlas: they are thin and loose. lateral portions are directed obliquely upwards and medialwards, a reinforced by bundles of fibres, which are attached above to the jugul cesses of the occipital bone, and below to the bases of the transverse pr of the atlas.

The atlanto-occipital joints frequently communicate with the joint b the dens and the transverse ligament of the atlas.

The **anterior atlanto-occipital membrane** (fig. 473) is broad, an posed of densely woven fibres which pass between the anterior margin foramen magnum above, and the upper border of the anterior arch of th below; laterally, it is continuous with the articular capsules; in front strengthened in the middle line by the continuation of the anterior longi ligament, a strong, rounded cord, which connects the basilar part of the o bone to the tubercle on the anterior arch of the atlas.

The **posterior atlanto-occipital membrane** (fig. 474), broad but th connected, above, to the posterior margin of the foramen magnum; bel the upper border of the posterior arch of the atlas. On either side it o over the groove for the vertebral artery, and with this groove bounds an o for the entrance of the artery and the exit of the first cervical nerve free border of the membrane, arching over the artery and nerve, is som ossified.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Movements.—The movements permitted in this joint are (*a*) flexion and extension, which give rise to the ordinary forward and backward nodding of the head, (*b*) slight lateral motion to one or other side.

Muscles producing the movements:

Flexion.—Longus capitis and Rectus capitis anterior.

Extension.—Recti capitis posteriores major et minor, Obliquus superior, Semispinalis capitis, Splenius capitis, Sternocleidomastoideus and Trapezius (upper fibres).

Lateral flexion.—Rectus capitis lateralis, Semispinalis capitis, Splenius capitis, Sternocleidomastoideus and Trapezius (upper fibres).

2. The Ligaments connecting the Epistropheus with the Occipital Bone

Membrana tectoria. Two alar. Ligamentum apicis dentis.

The **membrana tectoria** (occipito-axial ligament) (figs. 476, 477) is situated within the vertebral canal. It is a broad, strong band, which covers the dens with its ligaments, and appears to be a prolongation upwards of the posterior longitudinal ligament of the vertebral column. It is fixed, below, to the posterior surface of the body of the epistropheus, and, expanding as it ascends, is attached above to the upper surface of the basilar part of the occipital bone, in front of the foramen magnum, blending with the cranial dura mater.

The **alar ligaments** (odontoid ligaments) (fig. 476) are two strong, rounded cords, which arise one on either side of the upper part of the dens, and passing obliquely upwards and lateralwards, are inserted into rough impressions on the medial sides of the condyles of the occipital bone. The alar ligaments limit rotation of the cranium and therefore receive the name of *check ligaments*.

Between the alar ligaments is the **ligamentum apicis dentis** (fig. 477) which extends from the tip of the dens to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior atlanto-occipital membrane and with the superior crus of the transverse ligament of the atlas. It is regarded as a rudimentary intervertebral fibrocartilage, and traces of the notochord may persist in it.

In addition to the ligaments which unite the atlas and epistropheus to the skull, it must be remembered that the ligamentum nuchæ (p. 361) connects the cervical vertebræ with the cranium.

Applied Anatomy.—The ligaments of the vertebral column are so strong, and the joints so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, except in the upper part of the neck, rarely occurs unless accompanied by fracture. Dislocation of the occipital bone from the atlas has been recorded in one or two cases; but dislocation of the atlas from the epistropheus, with rupture of the transverse ligament of the atlas, is much more common; it is the mode in which death is produced in many cases of execution by hanging. Hanging may however produce a fracture through the epistropheus, or a separation through the fibrocartilage between the epistropheus and the third cervical vertebra. Below the third cervical vertebra, dislocation without fracture occasionally takes place.

THE COSTOVERTEBRAL ARTICULATIONS

The articulations of the ribs with the vertebral column may be divided into two sets, one connecting the heads of the ribs with the bodies of the vertebræ, the other uniting the necks and tubercles of the ribs with the transverse processes.

1. The Articulations of the Heads of the Ribs (fig. 478)

These articulations, sometimes named the *costocentral*, constitute a series of arthrodial joints. They are formed by the articulation of the heads of the thoracic ribs with the facets on the contiguous margins of the bodies of the thoracic vertebræ and with the intervertebral fibrocartilages between them; the first,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tenth, eleventh, and twelfth ribs each articulate with a single vertebra, the ligaments of the joints are :

The articular capsules. Radiate.
Interarticular.

In the articulations of the heads of the ribs from the second to the tenth, inclusive, two articular capsules are present, since each of these joints is divided by an interarticular ligament. The **articular capsules** connect the heads of the ribs with the circumferences of the articular cavities formed by the intervertebral fibrocartilages and the adjacent vertebræ. Some of the upper fibres pass through the intervertebral foramen to the back of the intervertebral fibrocartilage, while the posterior fibres are continuous with the ligament of the neck of the rib.

FIG. 478.—The costovertebral articulations. Right antero-lateral aspect.

The **radiate ligament** (stellate ligament) connects the anterior part of the head of each rib with the sides of the bodies of two vertebræ, and the intervertebral fibrocartilage between them. It is attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres are short and are connected with the body of the vertebra above ; the inferior fibres descend to the body of the vertebra below ; the middle fibres, the smallest and least distinct, are horizontal and attached to the intervertebral fibrocartilage.

In the articulation of the first rib, the radiate ligament is attached to the body of the last cervical vertebra, as well as to that of the first thoracic. In the articulations of the tenth, eleventh, and twelfth ribs, each of which articulates with a single vertebra, the radiate ligament is connected to the vertebra with which the rib articulates, and also to the vertebra immediately above.

The **interarticular ligament** is situated in the interior of the joint, and consists of a short band of fibres, flattened from above downwards, attached laterally to the crest separating the two articular facets on the head of the rib, and medially to the intervertebral fibrocartilage ; it divides the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

two cavities and its upper and lower surfaces are covered with the synovial ta of the articular capsules. In the joints of the first, tenth, eleventh, and lfth ribs, interarticular ligaments do not exist; consequently, there is but cavity in each of these articulations. The interarticular ligament is the logue of the *ligamentum conjugale* which is present in some mammals, and s the heads of opposite ribs across the back of the intervertebral fibro-ilage.

2. The Costotransverse Articulations (fig. 479)

The articular portion of the tubercle of a rib forms an arthrodial joint with transverse process of the lower of the two vertebræ to which the head of rib is fixed. In the eleventh and twelfth ribs this articulation is wanting. The ligaments of the joint are:

The articular capsule.
Anterior and posterior costotransverse.
Ligament of the neck of the rib.
Ligament of the tubercle of the rib.

The **articular capsule** is a thin membrane attached to the circumference e articular surfaces, and lined with a synovial stratum.

Fig. 479.—The costotransverse articulations. Superior aspect.

The **anterior costotransverse ligament** is attached below to the crest the upper border of the neck of the rib, and passes obliquely upwards and lwards to the lower border of the transverse process immediately above. The first rib has no anterior costotransverse ligament. The neck of the fth rib is connected to the base of the transverse process of the first lumbar ebra by a band of fibres, named the *lumbocostal ligament*; it is in series the anterior costotransverse ligaments.

The **posterior costotransverse ligament** is a feeble band which is ched below to the neck of the rib, behind and medial to the anterior transverse ligament; it passes upwards and medialwards to the base of transverse process and the lateral border of the inferior articular process of vertebra above.

The **ligament of the neck of the rib** (interosseous costotransverse ment) consists of short but strong fibres, connecting the rough surface the back of the neck of the rib with the anterior surface of the adjacent verse process. A rudimentary ligament may be present at the eleventh twelfth ribs.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **ligament of the tubercle of the rib** is a short, thick fasciculus, which passes obliquely from the apex of the transverse p the rough non-articular portion of the tubercle of the rib. The l attached to the upper ribs ascend from the transverse processes, shorter and more oblique than those at the lower ribs, which descend slightly.

FIG. 480.—A section through the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper with the flattened facets on the lower transverse processes.

Movements.—The heads of the rib closely connected to the bodies of the by the radiate and interarticular ligam only slight gliding movements of the surfaces on one another can take place. the strong ligaments binding the necks and of the ribs to the transverse processes movements of the costotransverse slight gliding, the nature of which is de by the shape and direction of the artic faces (fig. 480). The articular surfaces tubercles of the upper six ribs are oval and convex from above downwards; into corresponding concavities on the surfaces of the transverse processes, upward and downward movements of the are associated with rotation of the rib its long axis. On the seventh, eight and tenth ribs the articular surfaces on the are flat, and are directed obliquely do medialwards, and backwards. The surfa which they articulate are placed on th margins of the transverse processes; therefore, the tubercles are drawn up at the same time carried backwards and wards. The two joints, costocentral a transverse, move simultaneously and in t directions, the total effect being that the the rib moves as if on a single joint, of w costocentral and costotransverse articulati the ends. In the upper six ribs the neck rib moves but slightly upwards and dow its chief movement is one of rotation r own long axis, rotation backwards being a with depression, rotation forwards with elevation. In the seventh, eight and tenth ribs the neck of the rib moves upwards, backwards, and medi or downwards, forwards, and lateralwards; very slight rotation accompan movements.

Muscles producing the movements.—These are discussed with the mu of respiration (p. 468).

THE STERNOCOSTAL ARTICULATIONS (fig. 481)

The cartilages of the true ribs, with the exception of the first, ar with the sternum by arthrodial joints. The cartilage of the first rib is d united with the sternum, and the joint between this rib and the ster a synchondrosis.

The ligaments of the arthrodial joints are :

The articular capsules.	Interarticular sternocostal.
Radiate sternocostal.	Costoxiphoid.

The **articular capsules** surround the joints between the sternu the cartilages of the ribs from the second to the seventh inclusive. Th very thin, intimately blended with the radiate sternocostal ligamen strengthened at the upper and lower parts of the articulations by a few which connect the cartilages to the side of the sternum.

The radiate sternocostal ligaments are broad, thin membranous bands h radiate from the front and back of the sternal ends of the cartilages e true ribs to the anterior and posterior surfaces of the sternum. Their ficial fibres intermingle with the fibres of the ligaments above and below with those of the opposite side, and on the front of the sternum with

ig. 481.—The sternocostal and interchondral articulations. Anterior aspect.

tendinous fibres of origin of the Pectoralis major, forming a thick fibrous mbrane (*membrana sterni*) which envelops the bone, and is more distinct s lower than at its upper part.

The interarticular sternocostal ligaments are found constantly only een the second costal cartilages and the sternum. The cartilage of the *rib* is connected with the sternum by means of an interarticular ligament, ched laterally to the cartilage of the rib, and medially to the fibrocartilage h unites the manubrium and body of the sternum. Occasionally the tilage of the *third rib* is connected with the first and second pieces of the body

of the sternum by an interarticular ligament. Still more rarely, si
ments are found in the other four joints of the series. In the lowe
interarticular ligament sometimes obliterates the joint-cavity, so as t
the articulation into an amphiarthrosis. After middle life the articula
lose their polish, become roughened, and the synovial strata appar
appear. In old age, the cartilages of most of the ribs become contin
the sternum, and the joint-cavities are consequently obliterated.

The **costoxiphoid ligaments** connect the anterior and posterior
of the seventh costal cartilage, and sometimes those of the sixth, to
and back of the xiphoid process. They vary in length and breadth in
subjects; those on the back of the joint are less distinct than those in

Movements.—Slight gliding movements are permitted in the st
articulations.

The Interchondral Articulations (fig. 481)

The contiguous borders of the sixth and seventh, the seventh and
and the eighth and ninth, costal cartilages articulate with each other
smooth, oblong facets. Each articulation is enclosed in a thin *articular*
lined with a synovial stratum and strengthened laterally and medially
chondral ligaments which pass from one cartilage to the other. So
the fifth costal cartilages, more rarely the ninth, articulate by the
borders with the adjoining cartilages by small oval facets; more fr
the connexion is by a few ligamentous fibres.

The Costochondral Articulations

The lateral end of each costal cartilage is received into a depressi
sternal end of the rib, and the two are enveloped by the periosteum.

The Articulation of the Manubrium with the Body of the St

In the majority of cases the joint between the manubrium and th
of the sternum is a symphysis, the bony surfaces being coated with c
and connected by a disc of fibrocartilage which tends to ossify in a
life. In rather more than thirty per cent. of cases the central par
disc undergoes absorption and the joint is converted into a diarthro
The two segments of the bone are also connected by the membrana ster

The Mechanism of the Thorax

Each rib possesses its own range and variety of movements, but the mo
of all are combined in the respiratory excursions of the thorax. Each rib
regarded as a lever, the fulcrum of which is situated immediately outside th
transverse articulation, so that when the body of the rib is elevated the
depressed and *vice versa*; from the disproportion in length of the arms of th
a slight movement at the vertebral end of the rib is greatly magnified at the
extremity.

The anterior ends of the ribs lie on a lower plane than the posterior
therefore the body of the rib is elevated the anterior extremity is also thrust u
Again, the middle of the body of the rib lies in a plane below that passing thro
two extremities, so that when the body is elevated relatively to its ends
the same time carried outwards from the median plane of the thorax; furth
rib forms the segment of a curve which is greater than that of the rib imm
above. Therefore the elevation of a rib increases the transverse diameter
thorax in the plane to which it is raised. The modifications of the rib mo
at their vertebral ends have already been described (p. 370). Further m
tions result from the attachments of their anterior extremities, and it is con
therefore to consider separately the movements of the ribs of the three g
vertebrosternal, vertebrochondral, and vertebral.

ixth ribs raises and thrusts forwards their anterior extremities, the greater of the movement being effected by the rotation of the rib-neck backwards.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The thrust of the anterior extremities carries forwards and upwards the sternum, which moves on the joint between it and the manubrium; the anteroposterior thoracic diameter is increased. This movement is soon arrested, and the elevating force is then expended in raising the body of the rib and everting its lower border; at the same time the chondral angle is opened out. By these latter movements a considerable in the transverse diameter of the thorax is effected.

Vertebrochondral ribs (fig. 484).—The seventh rib is included with the as it conforms more closely to their type. While the movements of these in enlarging the thorax for respiratory purposes, they are also concerned in the upper abdominal space for viscera displaced by the action of the D The costal cartilages articulate with one another, so that each pushes up it, the final thrust being directed to pushing forwards and upwards the of the body of the sternum. The amount of elevation of the anterior is limited on account of the very slight rotation of the rib-neck. El the shaft is accompanied by an outward and backward movement; the movement everts the anterior end of the rib and opens up the subcost while the backward movement pulls back the anterior extremity and co the forward thrust due to its elevation; this latter is most noticeable in ribs, which are the shortest. The total result is a considerable increa transverse and a diminution in the median anteroposterior diameter of part of the abdomen; at the same time, however, the lateral anter diameters of the abdomen are increased.

Vertebral ribs.—Since these ribs have free anterior extremities and central articulations with no interarticular ligaments, they are capable movements in all directions. When the other ribs are elevated these are and fixed to form points of action for the Diaphragm.

Muscles producing the movements.—These are discussed with the of respiration (p. 468).

THE ARTICULATIONS OF THE UPPER EXTREMITY

The articulations of the upper extremity comprise the following:

I. The sternoclavicular.
II. The acromioclavicular.
III. The humeral (shoulder).
IV. The cubital (elbow).
V. The radio-ulnar.
VI. The radiocarpal (wr
VII. The intercarpal.
VIII. The carpometacarp
IX. The intermetacarp
X. The metacarpophal
XI. The digital.

I. THE STERNOCLAVICULAR ARTICULATION (fig. 485)

The sternoclavicular articulation is a double arthrodial joint, the cavity being subdivided by an articular disc. The parts entering formation are the sternal end of the clavicle, the lateral part of the border of the manubrium sterni, and the cartilage of the first rib. The surface of the clavicle is much larger than that of the sternum, and is with a layer of cartilage,* which is considerably thicker than that sternum. The ligaments of this joint are:

The articular capsule.
Sternoclavicular.
Interclavicular.
Costoclavicular.

The **articular capsule** surrounds the articulation; in front and it is of considerable thickness, but above, and especially below, it is partakes more of the character of areolar than of true fibrous tissue.

The **sternoclavicular ligament** is a broad band, covering the anterior face of the articulation; it is attached above to the upper and front part

* According to Bruch, the sternal end of the clavicle is covered by a tissue which is rather than cartilaginous in structure.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

nal end of the clavicle, and, passing obliquely downwards and medialwards, ttached below to the front of the upper part of the manubrium sterni.

The **interclavicular ligament** is continuous above with the fascia colli e cervical fascia); it passes from the upper part of the sternal end of clavicle to that of the other, and is also attached to the upper margin e manubrium sterni.

The **costoclavicular ligament** (rhomboid ligament) is short, flat, strong, rhomboid in form. Attached below to the upper surface of the cartilage e first rib, it ascends backwards and lateralwards, and is fixed above to costal tuberosity on the under surface of the clavicle.

FIG. 485.—The sternoclavicular articulations. Anterior aspect.

The **articular disc** is flat and nearly circular, and is interposed between the ulating surfaces of the sternum and clavicle. It is attached, above to upper and posterior border of the articular surface of the clavicle; below e cartilage of the first rib, near its junction with the sternum; and by rest of its circumference to the articular capsule. It is thicker at the mference than at the centre, and divides the joint into two cavities; each surfaces is clothed with a synovial stratum.

The *arteries* supplying the joint are derived from the internal mammary ansverse scapular arteries; the *nerves*, from the anterior supraclavicular s.

Movements.—This articulation admits of a limited amount of movement in nearly direction—upwards, downwards, backwards, forwards, as well as circum- on. When these movements take place in the joint, the clavicle in its motion s the scapula with it, this bone gliding on the outer surface of the chest. This therefore forms the centre from which all movements of the supporting arch e shoulder originate, and is the only point of articulation of the shoulder-girdle the trunk. The movements attendant on elevation and depression of the der take place between the clavicle and the articular disc. When the shoulder ved forwards and backwards, the clavicle, with the articular disc, rolls to and n the articular surface of the sternum. Elevation of the shoulder is limited rally by the costoclavicular ligament; depression, by the interclavicular ent and articular disc.

plied Anatomy.—The strength of this joint depends upon its ligaments, and lly on the articular disc. It is owing to these, and to the fact that the force of the usually transmitted along the long axis of the clavicle, that dislocation rarely , and that the clavicle is broken rather than displaced. Dislocation may be either is, backwards or upwards. Should the clavicle be displaced backwards it may pressure on the trachea and great vessels of the neck. The chief point worthy of as regards the construction of the joint, in connexion with dislocation, is the fact owing to the shape of the articular surfaces, and the strength of the joint mainly ing upon the ligaments, the displacement when reduced is very liable to recur.

II. THE ACROMIOCLAVICULAR ARTICULATION

The acromioclavicular articulation (fig. 486) is an arthrodial joint between the acromial end of the clavicle and the medial margin of the acromion of the scapula. Its ligaments are :

The articular capsule.
Acromioclavicular.
Coracoclavicular { Trapezoid and Conoid.

The **articular capsule** completely surrounds the articular margins, and is strengthened above by the acromioclavicular ligament.

FIG. 486.—The ligaments of the left scapula and shoulder-joint. Anterior aspect.

The **acromioclavicular ligament** is a quadrilateral band, covering the superior part of the articulation, and extending between the upper surface of the acromial end of the clavicle and the adjoining part of the upper surface of the acromion ; it is composed of parallel fibres, which interlace with the aponeuroses of the Trapezius and Deltoideus.

An **articular disc** is sometimes found in this joint ; when present it generally occupies the upper part of the articulation, and only partially separates the articular surfaces. More rarely, it completely divides the joint into two cavities.

The **coracoclavicular ligament** (fig. 486) connects the clavicle with the coracoid process of the scapula. It does not properly belong to the acromioclavicular articulation, but is usually described with it since it forms the efficient means of retaining the clavicle in contact with the acromion. It consists of two parts, viz. the *trapezoid* and *conoid ligaments*, which are separated by a bursa.

The *trapezoid ligament*, the anterior and lateral fasciculus, is broad and quadrilateral. It is attached, below, to the upper surface of the coracoid process ; above, to the oblique ridge on the under surface of the clavicle.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

anterior border is free, its posterior is joined with the conoid ligament, two forming, by their junction, an angle projecting backwards.

The *conoid ligament*, the posterior and medial fasciculus, is a dense band of s, conical in form, with its base directed upwards. Its apex is attached rough impression at the junction of the ascending and horizontal portions e coracoid process, medial to the trapezoid ligament; its base is fixed e coracoid tuberosity on the under surface of the clavicle, and to a line ceding medialwards from it for 1·25 cm.

The *arteries* supplying the joint are derived from the transverse scapular thoraco-acromial arteries; the *nerve* is a branch of the suprascapular e.

Movements.—The movements of this articulation are of two kinds: (1) a gliding on of the articular end of the clavicle on the acromion; (2) rotation of the ula forwards and backwards upon the clavicle. The extent of this rotation is ed by the two portions of the coracoclavicular ligament, the trapezoid limiting ion forwards, and the conoid backwards.

The acromioclavicular joint has important functions in the movements of the r extremity. Humphry * pointed out that if there had been no joint between lavicle and scapula, the circular movement of the scapula on the ribs (as in ing the shoulders backwards or forwards) would have been attended with ter alteration in the direction of the shoulder than is consistent with the se of the arm in such positions, and it would have been impossible to give w straight forwards with the full force of the arm: that is to say, with the ined force of the scapula, arm, and forearm. 'This joint,' as he happily ' is so adjusted as to enable either bone to turn in a hinge-like manner upon a al axis drawn through the other, and it permits the surfaces of the scapula, the baskets in a roundabout swing, to look the same way in every position, or y so.' Again, when the whole arch formed by the clavicle and scapula rises falls (in elevation or depression of the shoulder), the joint between these two s enables the scapula still to maintain its lower part in contact with the ribs.

plied Anatomy.—The acromioclavicular joint owes its security mainly to the coclavicular ligament. Owing to the slanting shape of the articular surfaces of this dislocation generally occurs upwards; that is to say, the acromial end of the clavicle placed above the acromion of the scapula. The displacement is often incomplete, ccount of the strong coracoclavicular ligaments, which remain untorn. The same ility exists, as in the sternoclavicular dislocation, in maintaining the end of the bone sition after reduction.

THE LIGAMENTS OF THE SCAPULA

he ligaments of the scapula (fig. 486) are the coraco-acromial, and the rior and inferior transverse.

The **coraco-acromial ligament** is a strong triangular band, extending een the coracoid process and the acromion. Its apex is attached to the e of the acromion just in front of the articular surface for the clavicle; its base to the whole length of the lateral border of the coracoid process. ligament, together with the coracoid process and the acromion, forms an for the protection of the head of the humerus. It sometimes consists o strong marginal bands and a thinner intervening portion, the two bands attached respectively to the apex and the base of the coracoid process, joining together at the acromion.

When the Pectoralis minor is inserted, as it is occasionally, into the ule of the shoulder-joint instead of into the coracoid process, the tendon e muscle passes between the two bands of the coraco-acromial ligament.

The **superior transverse ligament** (suprascapular ligament) converts the lar notch into a foramen, and is sometimes ossified. It is a thin and sciculus, narrower at the middle than at the extremities, which are attached e base of the coracoid process and the medial end of the scapular notch tively. The suprascapular nerve runs through the foramen; the trans- e scapular vessels cross over the ligament.

The **inferior transverse ligament** (spinoglenoid ligament) is a membranous band, stretching from the lateral border of the spine of the scapula to the margin of the glenoid cavity. It forms an arch under which the transverse scapular vessels and suprascapular nerve enter the infraspinous fossa. It is frequently absent.

III. THE HUMERAL ARTICULATION OR SHOULDER-JOINT

The shoulder-joint (figs. 486 to 489) is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the hemispherical head of the humerus and the shallow glenoid cavity of the scapula, a construction which allows of very considerable movement, while the joint itself is protected by

FIG. 487.—A section through the shoulder-joint.

displacement, by the muscles which surround it. The joint is also protected above by an arch, formed by the coracoid process, the acromion, and the coraco-acromial ligament. The articular cartilage on the head of the humerus is thicker at the centre than at the circumference, the reverse being true with the articular cartilage of the glenoid cavity. The ligaments of articulation are :

The articular capsule.	The glenoidal labrum.
Coracohumeral.	Transverse humeral.

The **articular capsule** (figs. 486 to 488) envelops the joint, and is attached above, to the circumference of the glenoid cavity beyond the glenoidal labrum; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage at the upper than at the lower part of the neck. It is lax above and below than elsewhere, and is so remarkably loose and lax that the bones may be separated from each other for a distance of 2 or 3 cm. This evident provision for the great freedom of movement which is permitted by this articulation. It is strengthened, above, by the Supraspinatus; in front, by the long head of the Triceps brachii ; behind, by the tendons of the Infraspinatus and Teres minor; and in front, by the tendon of the Subscapularis.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are usually three openings in the capsule. One anteriorly, below the oid process, establishes a communication between the joint and a bursa th the tendon of the Subscapularis; another, between the tubercles of the us, gives passage to the long tendon of the Biceps brachii; the third, is not constant, is at the posterior part, between the joint and a bursal nder the tendon of the Infraspinatus.

hree supplemental bands (fig. 489) which are named the *glenohumeral onds*, strengthen the capsule. These are best seen by opening the posterior of the capsule of the joint and removing the head of the humerus. At scapular ends they are all attached to the upper part of the medial margin

ig. 488.—The articular capsule of the right shoulder-joint (distended). Anterior aspect. (From a specimen prepared by J. C. B. Grant.)

glenoid cavity and are intimately connected with the glenoidal labrum. superior band passes along the medial edge of the tendon of Biceps brachii attached to a small depression above the lesser tubercle of the humerus; middle band reaches the lower part of the lesser tubercle; the inferior band ds to the lower part of the anatomical neck of the humerus. In addition se, the capsule is strengthened in front by two bands, one derived from endon of the Pectoralis major, the other from the tendon of the Teres r.

he *synovial stratum* is reflected from the margin of the glenoid cavity over enoidal labrum; it is then continued over the inner surface of the capsule, overs the lower part and sides of the anatomical neck of the humerus as the articular cartilage on the head of the bone. The tendon of the long of the Biceps brachii passes through the fibrous stratum of the capsule s enclosed in a tubular sheath of the synovial stratum, which is reflected it from the summit of the glenoid cavity and is continued round the into the intertubercular sulcus as far as the surgical neck of the humerus 88).

he **coracohumeral ligament** is a broad band which strengthens the part of the capsule. It arises from the lateral border of the root of racoid process, and passes obliquely downwards and lateralwards to the of the greater tubercle of the humerus, blending with the tendon of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the Supraspinatus. The hinder and lower border of the ligament to the capsule; its anterior and upper border is free, and overlaps the lesser to the greater tubercle of the humerus; it converts the inter sulcus into a canal, and its attachment is always limited to that the bone which lies above the epiphysial line.

The **glenoidal labrum** (glenoid ligament) (fig. 489) is a fibrocartilage attached round the margin of the glenoid cavity. It is triangular the base being fixed to the circumference of the cavity, while the is thin and sharp. It is continuous above with the tendon of the of the Biceps brachii, which gives off two fasciculi to blend with tissue of the labrum. It deepens the articular cavity, and protects of the bone. Its attachment to the margin of the glenoid cavity is deficient in parts; the deficiency occurs most commonly at the upper part of the medial margin, and a small fringe of the synovial occasionally protrudes through the gap.

Fig. 489.—Interior of shoulder-joint. Lateral aspect.

Bursæ.—The bursæ in the neighbourhood of the shoulder-joint are the (1) one is constantly found between the tendon of the Subscapularis and capsule: it communicates with the synovial cavity through an open front of the capsule; (2) one is sometimes found between the tendon of spinatus and the capsule; it occasionally opens into the joint; (3) a exists between the under surface of the Deltoideus and the capsule, but communicate with the joint: this bursa is prolonged under the acro coraco-acromial ligament, and intervenes between these structures and the (4) a large one is situated on the summit of the acromion; (5) one is found between the coracoid process and the capsule; (6) one exists be Coracobrachialis; (7) one lies between the Teres major and the long he Triceps brachii; (8) one is placed in front of, and another behind, the the Latissimus dorsi.

The *muscles* in relation with the joint are, above, the Supraspinatus the long head of the Triceps brachii; in front, the Subscapularis; be Infraspinatus and Teres minor; within, the tendon of the long head of brachii. The Deltoideus covers the articulation in front, behind, and

The *arteries* supplying the joint are derived from the anterior and humeral circumflex, and transverse scapular arteries; the *nerves*, from the (circumflex) and suprascapular nerves.

ovements.—The shoulder-joint is capable of flexion, extension, abduction, ion, circumduction, and rotation.

e most striking peculiarities in this joint are: 1. The large size of the head humerus in comparison with the depth of the glenoid cavity, even though the s supplemented by the glenoidal labrum. 2. The looseness of the capsule joint. 3. The intimate connexion of the capsule with the muscles attached tubercles of the humerus. 4. The peculiar relation of the tendon of the long f the Biceps brachii to the joint.

is in consequence of the relative sizes of the two articular surfaces, and the ess of the articular capsule, that the joint enjoys such free movement in all ons. When these movements of the arm are arrested in the shoulder-joint contact of the bony surfaces, and by the tension of the fibres of the capsule er with that of the muscles acting as accessory ligaments, the arm can be considerably farther by the movements of the scapula, involving, of motion at the sternoclavicular and acromioclavicular joints. These joints erefore to be regarded as accessory to the shoulder-joint (pp. 374 to 377). xtent of the scapular movements is very considerable, especially in extreme on of the arm, a movement best accomplished when the arm is thrown hat forwards and outwards, because the margin of the head of the humerus o means a true circle; the greatest diameter of the head is from the ercular groove, downwards, medialwards, and backwards, and the greatest n of the arm can be obtained by rolling its articular surface in the direction measurement.

e looseness of the capsule is so great that the arm will fall 2 or 3 cm. from pula when the muscles are dissected from the capsule, and an opening made o counteract the atmospheric pressure. The movements of the joint, there- re not regulated by the capsule so much as by the surrounding muscles, an ement which 'renders the movements of the joint much more easy than ould otherwise have been, and permits a swinging, pendulum-like vibration limb when the muscles are at rest' (Humphry). The fact, also, that in all ry positions of the joint the capsule is not put on the stretch, enables the arm e freely in all directions. Extreme movements are checked by the tension opriate portions of the capsule, as well as by the interlocking of the bones. t is said that 'abduction is checked by the contact of the great tuberosity e upper edge of the glenoid cavity; adduction by the tension of the coraco- al ligament' (Beaunis and Bouchard). Cleland * maintains that the limita- t movement at the shoulder-joint are due to the structure of the joint itself, enoidal labrum fitting, in different positions of the elevated arm, into the ical neck of the humerus.

e scapula is capable of being moved upwards and downwards, and forwards kwards, and, by a combination of these movements, circumducted on the he chest. The mobility of the scapula is very considerable, and greatly he movements of the arm at the shoulder-joint. Thus, in raising the arm e side, the Deltoideus and Supraspinatus can only lift it to a right angle e trunk, the further elevation of the limb being effected by the Trapezius ratus anterior moving the scapula on the wall of the chest. This mobility ecial importance in ankylosis of the shoulder-joint, the movements of the compensating to a very great extent for the immobility of the joint.

kart † has pointed out that in abducting the arm and raising it above the he scapula rotates throughout the whole movement with the exception of space at the beginning and at the end; that the humerus moves on the not only while passing from the hanging to the horizontal position, but travelling upwards as it approaches the vertical above; that the clavicle not only during the second half of the movement but in the first as well, to a less extent—i.e. the scapula and clavicle are concerned in the first stage as in the second; and that the humerus is partly involved in the second as chiefly in the first.

peculiar relations of the tendon of the long head of the Biceps brachii to lder-joint appear to subserve various purposes. In the first place, by its on with both the shoulder and elbow the muscle harmonises the action two joints, and acts as an elastic ligament during all the movements

* *Journal of Anatomy and Physiology*, vol. xxiii.

which occur at these articulations. It strengthens the upper part of the joint, and prevents the head of the humerus from being pressed up against the acromion when the Deltoideus contracts; it thus fixes the head of the humerus as the centre of motion in the glenoid cavity. By its passage along the bicipital sulcus it assists in steadying the head of the humerus in the various movements of the arm. When the arm is raised from the side the Biceps brachii, the Supraspinatus and the Infraspinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents it slipping over the lower edge, and also from being pulled by the action of the Latissimus dorsi and Pectoralis major, as in climbing, and many other movements.

Muscles producing the movements.—The muscles moving the shoulder-joint are divided into: (*a*) those acting on the shoulder-girdle, and (*b*) those acting on the shoulder-joint.

(*a*) **Muscles acting on the shoulder-girdle.**—The chief effect of these muscles is to displace the point of the shoulder, either by pulling directly on the shoulder-girdle or by rotating the scapula. The terms elevation, depression, etc., therefore refer to the point of the shoulder.

Elevation.—Trapezius, Levator scapulæ, Serratus anterior.
Depression.—Pectoralis minor, Rhomboideus major, Subclavius.
Forward movement.—Pectoralis minor, Serratus anterior, Subclavius.
Backward movement.—Trapezius, Levator scapulæ, Rhomboidei.

(*b*) **Muscles acting on the shoulder-joint.**

Flexion.—Subscapularis, Deltoideus (anterior part), Pectoralis major (clavicular head), Coracobrachialis, Biceps brachii.
Extension.—Infraspinatus, Teres minor, Teres major, Latissimus dorsi, Triceps brachii (long head).
Abduction.—Supraspinatus, Deltoideus.
Adduction.—Subscapularis, Infraspinatus, Teres minor, Pectoralis major, Latissimus dorsi, Teres major, Coracobrachialis, Biceps brachii, Triceps brachii.
Rotation inwards.—Subscapularis, Pectoralis major, Latissimus dorsi, Teres major.
Rotation outwards.—Infraspinatus, Teres minor, Deltoideus (posterior).

Applied Anatomy.—Owing to the construction of the shoulder-joint and the kind of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint. Dislocation occurs when the arm is forced, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rupture of the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, between the tendons of Subscapularis and the Triceps brachii, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front of and behind the joint. As the muscles in the back are stronger than those in front, and especially since the long head of the Triceps brachii prevents the bone from passing backwards, dislocation forwards is much more common. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence is subcoracoid. Occasionally, in consequence of a greater amount of force being brought to bear on the limb, the head is driven farther medialwards, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backwards and remains in the infraspinous fossa, beneath the spine (subspinous). If, after the dislocation has been reduced, motion of the arm is prevented, the dislocation cannot recur.

Synovitis is attended with effusion into the joint, and when this occurs the joint is evenly distended, and the contour of the joint rounded. Special projections occur at the sites of the openings in the capsule. Thus a swelling may appear just medial to the lesser tubercle, from effusion into the bursa beneath the Subscapularis; or a swelling which is sometimes bilobed may be seen in the interval between the Teres minor and Pectoralis major, from effusion into the diverticulum which runs down the tubercular groove with the tendon of the Biceps brachii. The effusion into the joint cavity can be best ascertained by examination from the axilla, where a soft fluctuating swelling may be felt. In cases of septic synovitis, where

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ed, the opening should be made in front, over the most prominent point of the ng. After the pus has been evacuated a counter-opening should be made behind, so nsure efficient drainage. In making this counter-opening care should be taken not re the axillary nerve, which here lies in contact with the joint-capsule.

e bursa under the Deltoideus may be distended with fluid; this condition may be en for effusion into the joint.

cision of the shoulder-joint may be required in cases of arthritis (especially the ulous form) which have gone on to destruction of the articulation; in compound tions and fractures, particularly those arising from gunshot injuries, in which has been extensive injury to the head of the bone; in some cases of old unreduced ation, where there is much pain. The operation is best performed by making an n from the middle of the coraco-acromial ligament down the arm for about 7 or , this will expose the intertubercular groove containing the tendon of the Biceps , which should be hooked out of the way. The articular capsule is freely opened, a muscles attached to the greater and lesser tubercles of the humerus are stripped th the capsule, without dividing their attachments to the latter. The head of the an then be thrust out of the wound and sawn off; or divided with a narrow saw and subsequently removed. The section should be made, if possible, just below icular surface, so as to leave the bone as long as possible.

hen the shoulder-joint is ankylosed, the loss of movement in the joint is partly nsated for by increased mobility of the scapula. In treating conditions of the er-joint likely to lead to ankylosis the humerus should be kept in the position it s when the palm of the hand is placed on the back of the neck, *i.e.* abducted, rotated inwards, and flexed anteriorly, so as to make full use of this compensating y of the scapula.

IV. THE CUBITAL ARTICULATION OR ELBOW-JOINT

e elbow-joint includes three articulations :—(1) *humero-ulnar*, between rochlea of the humerus and the semilunar notch of the ulna, (2) *humero-* between the capitulum of the humerus and the fovea on the head of dius, and (3) *proximal radio-ulnar*, where the circumference of the radial is retained in the circle formed by the annular ligament and the radial of the ulna (see p. 387). All three are included in a common articular le.

e humero-ulnar and humeroradial articulations together form a ginglymus ge-joint, the ligaments of which are :

The articular capsule.	Ulnar collateral.	Radial collateral.

e **articular capsule** (figs. 492 to 494).—The anterior part of the articular le is a broad and thin fibrous layer. It is attached, above, to the front of dial epicondyle and to the front of the humerus immediately above the l and radial fossæ ; below, to the anterior surface of the coronoid process ulna and to the annular ligament (p. 387), being continuous on either with the collateral ligaments. Its superficial fibres pass obliquely from edial epicondyle of the humerus to the annular ligament. The middle vertical in direction, pass from the upper part of the coronoid depression come partly blended with the preceding, but are inserted mainly into the or surface of the coronoid process. The deep or transverse set intersects at right angles. It is in relation, in front, with the Brachialis, except at st lateral part.

e posterior part of the articular capsule is thin and membranous, and s of transverse and oblique fibres. Above, it is attached to the humerus diately behind the capitulum and close to the medial margin of the lea, to the margins of the olecranon fossa, and to the back of the lateral ndyle some little distance from the trochlea. Below, it is fixed to the and lateral margins of the olecranon, to the posterior part of the annular nt, and to the ulna behind the radial notch. The transverse fibres a strong fasciculus which bridges the olecranon fossa ; under cover of and a pouch of the synovial stratum and a pad of fat are displaced e upper part of the fossa when the joint is extended. In the fat are a attered fibrous bundles which pass from the deep surface of the transverse to the upper part of the fossa. It is in relation, behind, with the tendon e Triceps brachii and the Anconæus.

V. THE RADIO-ULNAR ARTICULATIONS

The articulation of the radius with the ulna is effected by ligaments which nect together the extremities and also the bodies of these bones. The aments may, consequently, be subdivided into three sets: 1, those of the ximal radio-ulnar articulation; 2, the middle radio-ulnar ligaments; those of the distal radio-ulnar articulation.

1. The Proximal Radio-ulnar Articulation

This articulation forms a trochoid or pivot-joint between the circumference the head of the radius and the ring formed by the radial notch of the ulna the annular ligament.

The **annular ligament** (orbicular ligament) (fig. 495) is a strong band fibres, which encircles the head of the radius, and retains it in contact with radial notch of the ulna. It forms about four-fifths of the osseofibrous

Fig. 495.—The annular ligament of the left radius. Superior aspect. The head of the radius has been sawn off and the bone dislodged from the ligament.

and is attached to the anterior and posterior margins of the radial notch; of its lower fibres are continued round below the notch and form at this a complete fibrous ring. Its upper border blends with the radial collateral ment and the anterior and posterior parts of the articular capsule of the r-joint, while from its lower border a thin loose membrane passes to be ched to the neck of the radius. A thickened band which extends from the ior border of the annular ligament below the radial notch to the neck of adius is known as the *quadrate ligament*. The *superficial surface* of the ular ligament is strengthened by the radial collateral ligament of the elbow, affords origin to part of the Supinator. Its *deep surface* is lined with a vial stratum which is continuous with that of the elbow-joint.

Movements.—The movements allowed in this articulation are limited to rotatory ements of the head of the radius within the ring formed by the annular ligament e radial notch of the ulna; rotation forwards being called *pronation*; rotation wards, *supination*.

2. The Middle Radio-ulnar Union

e bodies of the radius and ulna are connected by the oblique cord and tibrachial interosseous membrane.

e oblique cord (fig. 493) is a small, flattened band, extending from the l side of the tubercle of the ulna at the base of the coronoid process to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the radius a little below the radial tuberosity and its fibres run at right a
those of the interosseous membrane. It is sometimes wanting.

The **antibrachial interosseous membrane** is a broad and thin sh
fibres of which slant obliquely downwards and medialwards from the
osseous crest of the radius to that of the ulna; the lower part of the ma
is attached to the posterior of the two lines into which the interosseo
of the radius divides. Two or three bands are occasionally found on the
surface of this membrane; their fibres descend obliquely from the ulna t
the radius, i.e. at right angles to the other fibres. The membrane is d
above, commencing about 2 or 3 cm. below the tuberosity of the rad
broader in the middle than at either end; and presents an oval ape
little above its lower margin, for the passage of the volar interosseous
to the back of the forearm. Between its upper border and the oblic
is a gap, through which the dorsal interosseous vessels pass. The me
connects the bones, and increases the extent of surface for the attach
the deep muscles of the forearm. It also transmits to the ulna and
to the humerus any force acting upwards through the hand and rad
is relaxed in complete pronation or supination, and is tense when the
midway between the prone and supine positions. *In front*, the memb
in relation, in its upper three-fourths, with the Flexor pollicis longus
radial side, and with the Flexor digitorum profundus on the ulnar side; b
these muscles are the volar interosseous vessels and nerve; in its low
fourth with the Pronator quadratus; *behind*, with the Supinator, Ab
pollicis longus, Extensor pollicis brevis, Extensor pollicis longus, E
indicis proprius; and, near the wrist, with the volar interosseous arte
dorsal interosseous nerve.

3. The Distal Radio-ulnar Articulation

This is a pivot-joint formed between the head of the ulna and th
notch of the lower end of the radius; the surfaces are enclosed in an a
capsule and held together by an articular disc.

The **articular capsule** is slightly thickened in front and behind;
it is lax, and with the synovial stratum, projects upwards as a pouch (
sacciformis) between the radius and the ulna.

The **articular disc** (fig. 498), triangular in shape, binds the lower
the ulna and radius firmly together. Its periphery is thicker than its
which is occasionally perforated. It is attached by its apex to a dep
between the styloid process and the head of the ulna; and by its base
is thin, to the prominent edge which separates the ulnar notch from the
articular surface of the radius. Its margins are united to the ligaments
wrist-joint. Its *proximal surface*, smooth and concave, articulates w
head of the ulna. Its *distal surface*, also smooth and concave, forms a
the radiocarpal joint and articulates with the medial part of the lunate
when the hand is adducted it articulates with the triquetral bone. B
its surfaces is clothed with a synovial stratum: the proximal, with that
distal radio-ulnar articulation; the distal, with that of the radiocarpal

Movements.—The movements of the three joints within the elbow s
studied together. The combination of the movements of flexion and exte
the forearm with those of pronation and supination of the hand, which is
by the two being performed at the same joint, is essential to the accurac
various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hin
and allows of movements of flexion and extension only, but owing to the
of the trochlea of the humerus, this movement does not take place in the
posterior plane of the body of the humerus. When the forearm is exten
supinated, the axes of the arm and forearm are not in the same line; the arm
an obtuse angle with the forearm, the hand and forearm being directed
wards. During flexion, however, the forearm and the hand tend to appro
middle line of the body, and thus enable the hand to be easily carried to
The accurate adaptation of the trochlea of the humerus, with its promin
depressions, to the semilunar notch of the ulna, prevents any lateral mov

The joint between the head of the radius and the capitulum of the humerus is arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis and allow of movement in all directions, were it not for the annular ligament, which the head of the radius is bound to the radial notch of the ulna, and which prevents any lateral separation of the two bones. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise tend to occur, from the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament, the tendon of the Biceps brachii would be liable to pull the head of the radius out of the joint. The head of the radius is not in complete contact with the capitulum of the humerus in all positions of the joint. The capitulum occupies only the anterior and inferior surfaces of the lower end of the humerus, so that in complete extension a part of the radial head can be easily felt projecting at the back of the articulation. In full flexion the movement of the radial head is hampered by the compression of the surrounding soft parts, and that the freest rotatory movement of the radius on the humerus (pronation and supination) takes place in semiflexion, in which position the two articular surfaces are in most intimate contact. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint; the limitation of flexion is also aided by the soft structures of the arm and forearm coming into contact.

In any position of flexion or extension, the radius, carrying the hand with it, is rotated in the proximal radio-ulnar joint. The hand is directly articulated with the lower surface of the radius only, and the ulnar notch on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint by the articular disc. Thus, rotation of the head of the radius about an axis passing through the centre of the capitulum of the humerus imparts similar movement to the hand through a very considerable arc.

The movements in the distal radio-ulnar articulation consist of rotation of the lower end of the radius round an axis which passes through the centre of the head of the ulna. When the radius rotates forwards, *pronation* of the forearm and hand is the result; and when backwards, *supination*. It will thus be seen that in pronation and supination the radius describes the segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement the head of the ulna is not stationary, but describes a curve in a direction opposite to that taken by the head of the radius. This, however, is not to be regarded as a rotation of the ulna—the curve which the head of the bone describes is due to a combined anteroposterior and rotatory movement taking place at the elbow-joint.

Muscles producing the movements.—These muscles may be grouped as (*a*) those acting on the humero-ulnar and humeroradial joints, and (*b*) those acting on the radio-ulnar joints.

(*a*) **Muscles acting on the humero-ulnar and humeroradial joints :**
Flexion.—Brachialis, Brachioradialis, Biceps brachii, Pronator teres.
Extension.—Triceps brachii, Anconæus.

(*b*) **Muscles acting on the radio-ulnar joints :**
Pronation.—Pronator teres, Pronator quadratus.
Supination.—Supinator, Biceps brachii.

Applied Anatomy.—From the breadth of the elbow-joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong collateral ligaments and the support which the joint derives from the mass of muscles attached to the condyles of the humerus, lateral displacement of the bones is very uncommon; whereas anteroposterior dislocation, on account of the shortness of the anteroposterior diameter, thickness of the anterior and posterior parts of the articular capsule, and the want of support of muscles, occurs much more frequently. Dislocation backwards takes place when the forearm is in a position of extension, and forwards when in a position of flexion. In the extended position, the coronoid process is not locked into the coronoid fossa, but loosely prevents displacement forwards. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backwards, while the olecranon, having left the olecranon fossa, is not so efficient in preventing a forward displacement. For the production of lateral dislocation it is necessary that the force should be applied laterally and that either the humerus or the bones of the forearm should be fixed. This is probably the chief reason why this dislocation is so rare; when it does occur it is generally incomplete. Dislocation of the elbow-joint is common in children.

The **ulnar collateral ligament** (internal lateral ligament) (figs. is attached to the end of the styloid process of the ulna; it divides fasciculi, one of which is fixed to the medial side of the triquetral other to the pisiform bone.

The **radial collateral ligament** (external lateral ligament) (figs. extends from the tip of the styloid process of the radius to the radial navicular bone, some of its fibres being prolonged to the greater mu bone. It is in relation with the radial artery, which separates the from the tendons of the Abductor pollicis longus and Extensor pollicis

FIG. 497.—The ligaments of the left wrist. Dorsal aspect.

The *arteries* supplying the joint are the volar interosseous, the volar and carpal branches of the radial and ulnar, the volar and dorsal metacarpal some recurrent branches from the deep volar arch. The *nerves* are derived the volar and dorsal interosseous nerves.

Movements.—The movements permitted in this joint are flexion, ext abduction, adduction, and circumduction. Flexion and extension are the mo and of these a greater amount of extension than of flexion is permitted, sin articulating surfaces extend farther on the dorsal than on the volar surfaces carpal bones. In this movement the carpal bones rotate on a transverse axis between the tips of the styloid processes of the radius and ulna. Adduc ulnar flexion, and abduction or radial flexion are also permitted. The for considerably greater in extent than the latter on account of the shortness styloid process of the ulna, abduction being soon limited by the contact of the process of the radius with the greater multangular bone. In this movem carpus revolves upon an anteroposterior axis drawn through the centre of the Finally, circumduction is permitted by the combined and consecutive move of adduction, extension, abduction, and flexion. No rotation is possible, b effect of rotation is obtained by the pronation and supination of the radius ulna.

* H. M. Johnston (*Journal of Anatomy and Physiology*, vol. xli.) maintains that in u radial flexion only slight lateral movement occurs at the radiocarpal joint, and that in c flexion and extension of the hand there is a small degree of ulnar flexion at the radiocarpal

VII. THE INTERCARPAL ARTICULATIONS

These articulations may be subdivided into three sets: (1) those of the imal row of carpal bones; (2) those of the distal row of carpal bones; (3) those of the two rows with each other.

1. The Articulations of the Proximal Row of Carpal Bones

These are arthrodial joints. The navicular, lunate, and triquetral are nected by dorsal, volar, and interosseous ligaments.

The **dorsal and volar ligaments**, two of each, are placed transversely ween the bones of the first row; they connect the navicular and lunate es, and the lunate and triquetral bones. The volar ligaments are weaker n the dorsal.

The **interosseous ligaments** (fig. 498) are two narrow bundles, one con- ting the lunate and navicular bones, the other the lunate and triquetral es. They are on a level with the proximal surfaces of these bones, and n part of the convex articular surface of the radiocarpal joint.

The ligaments of the pisiform bone are: an articular capsule, and the piso- te and pisometacarpal ligaments.

The **articular capsule** is thin and connects the pisiform to the triquetral. synovial stratum is distinct from that of the other carpal joints.

The **pisohamate ligament** connects the pisiform and hamate bones, and **pisometacarpal ligament** joins the pisiform bone to the base of the fifth tacarpal bone (fig. 496). These two ligaments are, in reality, prolonga- s of the tendon of the Flexor carpi ulnaris.

2. The Articulations of the Distal Row of Carpal Bones

These also are arthrodial joints; the bones are connected by dorsal, volar, interosseous ligaments.

The **dorsal and volar ligaments**, each three in number, extend transversely n one bone to another; one connects the greater and lesser multangular es, a second the lesser multangular and capitate bones, and a third the tate and hamate bones.

The three **interosseous ligaments** are much thicker than those of the imal row; one unites the capitate and hamate bones, a second the capitate lesser multangular bones, and a third the greater and lesser multangular s. The first is the strongest; the third is sometimes wanting.

3. The Articulations of the Two Rows of Carpal Bones with each other

The joint between the navicular, lunate, and triquetral bones on the one d, and the second row of carpal bones on the other, is named the *mid-carpal* t, and is made up of three portions: in the centre the head of the capitate e and the superior surface of the hamate bone articulate with the deep -shaped cavity formed by the navicular and lunate bones, and constitute rt of ball-and-socket joint; on the radial side the greater and lesser tangular bones articulate with the navicular bone, and on the ulnar side the te bone articulates with the triquetral bone, forming gliding joints.

The ligaments are: dorsal, volar, ulnar, and radial collateral.

The **dorsal and volar ligaments** consist of short, irregular bundles passing ween the bones of the first and second rows. On the volar surface the fibres ating from the head of the capitate bone to the surrounding bones form the *mentum carpi radiatum*.

The **collateral ligaments** are very short: one is placed on the radial, the er on the ulnar side of the carpus: the former, the stronger and more inct, connects the navicular and greater multangular bones, the latter the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

triquetral and hamate bones; they are continuous with the collateral l of the wrist-joint. In addition to these ligaments, a slender interosse sometimes connects the capitate and navicular bones.

The **synovial stratum of the carpus** is very extensive (fig. 4 bounds a cavity of very irregular shape. The proximal part of t intervenes between the distal surfaces of the navicular, lunate, and t bones and the proximal surfaces of the bones of the second row. It s prolongations upwards—between the navicular and lunate bones, and the lunate and triquetral bones—and three downwards between t

FIG. 498.—A vertical section through the articulations at the right wri showing the synovial cavities.

bones of the second row. The prolongation between the greater and multangular bones, or that between the lesser multangular and capitate is, owing to the absence of the interosseous ligament, often continuous the cavity of the carpometacarpal joints, sometimes of the second, fourth, and fifth metacarpal bones, sometimes of the second and third In the latter condition the joint between the hamate bone and the and fifth metacarpal bones has a separate synovial stratum. The sy cavities of these joints are prolonged for a short distance between the of the metacarpal bones. There is a separate synovial stratum betwe pisiform and triquetral bones.

Movements.—The chief movements permitted in the mid-carpal joint are and extension, flexion being freer than extension. A very slight amount of r is also permitted, the head of the capitate bone rotating round a vertic drawn through its own centre.

Muscles producing the movements:

Flexion.—Flexor carpi radialis, Flexor carpi ulnaris, Palmaris longus, F digitorum sublimis et profundus, Flexor pollicis longus.

Extension.—Extensores carpi radiales longus et brevis, Extensor carpi u Extensor digitorum communis, Extensores pollicis longus et b Extensor indicis proprius, Extensor digiti quinti proprius.

Adduction.—Flexor carpi ulnaris, Extensor carpi ulnaris.

Abduction.—Abductor pollicis longus, Extensores pollicis longus et b Extensor carpi radialis longus.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

pplied Anatomy.—The radiocarpal joint is rarely dislocated, its strength depending upon the numerous strong tendons which surround the articulation. Its security ther provided for by the number of small bones of which the carpus is made up, and are united by very strong ligaments. The slight movements which take place n the several bones serve to break the jars that result from falls or blows on the Dislocation backwards, which is the more common, simulates to a considerable Colles' fracture of the radius, and is liable to be mistaken for it. The differential is can be easily made by observing the relative positions of the styloid processes radius and the ulna. In the natural condition when the arm hangs by the side, radius is on a lower level, i.e. nearer the ground, than that of yloid process of the radius is not disturbed in dislocation. In Colles' fracture, the lna, and this relationship is on the same level as, or even on a higher level than, that d process of the radius is on the same level as, or even on a higher level than, that e ulna. A fracture of the lower end of the radius may be caused by a 'back-fire' rking a motor-car, and is named a chauffeur's fracture; there is usually little dis- ement and the fracture can only be detected by *x*-ray examination.

e radiocarpal joint is occasionally the seat of acute synovitis. When the joint y is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, r a general fulness, with some bulging between the tendons.

e grasp of the hand is strongest when the radiocarpal joint is hyperextended; the therefore, should be kept in this position during the treatment of any disease or injury to lead to ankylosis of the joint.

VIII. THE CARPOMETACARPAL ARTICULATIONS

1. The Carpometacarpal Articulation of the Thumb

This is a joint of reciprocal reception between the first metacarpal and r multangular bones; it enjoys great freedom of movement on account e configuration of its articular surfaces, which are saddle-shaped. The is surrounded by an **articular capsule** which is thick but loose, and s from the circumference of the base of the metacarpal bone to the rough bounding the articular surface of the greater multangular bone; it is est laterally and dorsally. A synovial stratum lines the capsule and te distinct from that of the other carpometacarpal joints (fig. 498).

ovements.—In this articulation the movements permitted are flexion, exten- bduction, adduction, circumduction, and opposition. It is by the movement position that the tip of the thumb is brought into contact with the volar surfaces slightly flexed fingers. This movement is effected through the medium of ll sloping facet on the anterior lip of the saddle-shaped articular surface of reater multangular bone. The flexor muscles pull the corresponding part articular surface of the metacarpal bone on to this facet, and the movement of tion is then carried out by the opponens and adductor muscles.

scles producing the movements:

Flexion.—Opponens pollicis, Flexores pollicis longus et brevis.

Extension.—Extensores pollicis longus et brevis.

Adduction.—Adductor pollicis, Opponens pollicis, Flexor pollicis brevis.

Abduction.—Abductor pollicis brevis, Extensores pollicis longus et brevis.

The Articulations of the Second, Third, Fourth, and Fifth Metacarpal Bones with the Carpus

he joints between the carpus and the second, third, fourth, and fifth meta- al bones are arthrodial. The bones are united by **articular capsules**, thened by dorsal, volar, and interosseous ligaments.

he **dorsal ligaments**, the strongest and most distinct, connect the carpal metacarpal bones on their dorsal surfaces. The second metacarpal bone s two fasciculi, one each from the greater and lesser multangular bones; hird metacarpal receives two, one each from the lesser multangular and te bones; the fourth two, one each from the capitate and hamate bones; h receives a single fasciculus from the hamate bone, and this is continuous a similar ligament on the volar surface, forming an incomplete fibrous ble.

he **volar ligaments** have a somewhat similar arrangement, with the tion of those of the third metacarpal bone, which are three in number: a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri
lateral one from the greater multangular bone, situated superficial sheath of the tendon of the Flexor carpi radialis; an intermediate the capitate bone; and a medial one from the hamate bone.

The **interosseous ligaments** consist of short, thick fibres, and to one part of the carpometacarpal articulation; they connect the inferior margins of the capitate and hamate bones with the adjacent of the third and fourth metacarpal bones.

The **synovial stratum** of the articular capsules is a continuation of the intercarpal joints. Occasionally, the joint between the hamate the fourth and fifth metacarpal bones has a separate synovial stratum.

Movements.—The movements permitted in the carpometacarpal of the fingers are limited to slight gliding of the articular surfaces upon the extent of which varies in the different joints. The metacarpal little finger is the most movable, then that of the ring-finger; the metacarpal of the index and middle fingers are almost immovable.

IX. THE INTERMETACARPAL ARTICULATIONS

The bases of the second, third, fourth, and fifth metacarpal bones with one another by small surfaces covered with cartilage, and are together by dorsal, volar, and interosseous ligaments.

The **dorsal and volar ligaments** pass transversely from one another on the dorsal and volar surfaces. The **interosseous ligaments** nect the contiguous surfaces of the bones, just distal to their collateral facets.

The **synovial stratum** of these joints is continuous with the carpometacarpal articulations.

The **transverse metacarpal ligament** (fig. 496) is a narrow fibrous which connects the volar surfaces of the heads of the second, third and fifth metacarpal bones. It is blended with the accessory volar (glenoid ligaments) of the metacarpophalangeal articulations. Its volar is grooved where the flexor tendons pass over it; the tendons of the pass behind the ligament.

X. THE METACARPOPHALANGEAL ARTICULATIONS

These articulations (figs. 499, 500) are of the condyloid kind, formed reception of the rounded heads of the metacarpal bones into shallow on the proximal ends of the first phalanges, with the exception of the thumb, which presents more of the characteristics of a ginglymoid joint joint has an accessory volar and two collateral ligaments.

The **accessory volar ligaments** (*glenoid ligaments* of Cruveilhier) thick, dense, fibrocartilaginous structures, placed upon the volar surface the joints in the intervals between the collateral ligaments, to which are connected; they are loosely united to the metacarpal bones, but firmly attached to the bases of the first phalanges. Their volar surface intimately blended with the transverse metacarpal ligament, and grooved the flexor tendons, the fibrous sheaths of which are connected to the of the grooves. Their deep surfaces form parts of the articular facets heads of the metacarpal bones.

The **collateral ligaments** are strong, rounded cords, placed on the of the joints; each is attached by one extremity to the posterior and adjacent depression on the side of the head of the metacarpal bone by the other to the side of the base of the phalanx.

The dorsal surfaces of these joints are covered with the expansion extensor tendons, together with some loose areolar tissue which the deep surfaces of the tendons to the bones.*

scles producing the movements :

Flexion.—Flexores digitorum sublimis et profundus, Lumbricales, Interossei dorsales et volares, Flexores pollicis longus et brevis, Flexor digiti quinti brevis.

Extension.—Extensor digitorum communis, Extensores pollicis longus et brevis, Extensor indicis proprius, Extensor digiti quinti proprius.

Adduction.—Interossei volares, Adductor pollicis, long flexors of fingers and thumb.

Abduction.—Interossei dorsales, Abductor pollicis brevis, Abductor digiti quinti, long extensors of fingers.

XI. THE DIGITAL ARTICULATIONS (figs. 499, 500)

he digital or interphalangeal articulations are hinge-joints; each has a volar two collateral ligaments. The arrangement of these ligaments is similar to in the metacarpophalangeal articulations. The extensor tendons supply aces of dorsal ligaments.

ovements.—The only movements permitted in the interphalangeal joints are n and extension; these movements are more extensive between the first and d phalanges than between the second and third. The amount of flexion is considerable, but extension is limited by the accessory volar ligaments.

ing a coronal section of the symphysis pubis near its posterior surface 503). In front, the lamina is strengthened by several superimposed layers fibres, which pass obliquely from one bone to the other, decussating and ing an interlacement with the fibres of the aponeuroses of the Obliqui rni and the medial tendons of origin of the Recti abdominis.

The Mechanism of the Pelvis

he pelvic girdle supports and protects the contained viscera and affords surfaces e attachments of the muscles of the trunk and lower limb. Its most important nical function, however, is to transmit the weight of the trunk and upper to the lower extremities.

t may be divided into two arches by a vertical plane passing through the aceta- cavities; the posterior of these arches is the one chiefly concerned in the n of transmitting the weight of the trunk. Its essential parts are the upper sacral vertebræ and two strong pillars of bone running from the sacro-iliac ulations to the acetabular cavities. For the reception and diffusion of the ht each acetabular cavity is strengthened by two additional bars running rds the os pubis and the ischium. In order to lessen concussion in rapid changes ribution of the weight, joints (sacro-iliac articulations) are interposed between crum and the iliac bones; an accessory joint (symphysis pubis) exists in the e of the anterior arch. The sacrum forms the summit of the posterior arch; eight transmitted falls on it at the lumbosacral articulation and, theoretically, component in each of two directions. One component of the force is expended ving the sacrum downwards and backwards between the iliac bones, while ther thrusts the upper end of the sacrum downwards and forwards towards elvic cavity.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The movements of the sacrum are regulated by its form. Viewed as it presents the shape of a wedge with its base upwards and forwards. component of the force is therefore acting against the resistance of the its tendency to separate the iliac bones is resisted by the sacro-iliac and ligaments and by the ligaments of the symphysis pubis.

FIG. 504.—A coronal section through the anterior sacral segment.

If a series of coronal sections be made through the sacro-iliac joints, found possible to divide the articular portion of the sacrum into three anterior, middle, and posterior. In the *anterior segment* (fig. 504), which the first sacral vertebra, the articular surfaces show slight sinuosities and parallel to one another. In the *middle segment* (fig. 505) the width bet dorsal margins of the sacral articular surfaces is greater than that bet ventral margins, and in the centre of each surface there is a concavity in a corresponding convexity of the iliac articular surface fits, forming an int mechanism. In the *posterior segment* (fig. 506) the ventral width of the is greater than the dorsal, and the articular surfaces are only slightly con

FIG. 505.—A coronal section through the middle sacral segment.

Dislocation downwards and forwards of the sacrum by the second co of the force applied to it is prevented therefore by the middle segme interposes the resistance of its wedge-shape and that of the interlocking m on its surfaces; a rotatory movement, however, is produced by which the segment is tilted downwards and the posterior upwards: the axis of this passes through the dorsal part of the middle segment. The movement anterior segment is slightly limited by its wedge-form, but chiefly by the and interosseous sacro-iliac ligaments; that of the posterior segment is ch a slight extent by its wedge-form, but the chief limiting factors are the tuberous and sacrospinous ligaments. In all these movements the effect

ischiocapsular ligaments. The external surface of the capsule is rough, ered by numerous muscles, and separated in front from the Psoas major d Iliacus by a bursa which not infrequently communicates through a ular aperture with the cavity of the joint.

The **synovial stratum** is very extensive. Commencing at the margin of cartilaginous surface of the head of the femur, it covers the portion of the k which is contained within the joint; from the neck it is reflected on internal surface of the fibrous stratum of the capsule, covers both surfaces the glenoidal labrum, ensheathes the ligamentum teres as far as the head

FIG. 509.—The right hip-joint. Anterior aspect.

the femur, and covers the mass of fat contained in the bottom of the aceta- lum. The joint-cavity sometimes communicates, through a hole between e vertical band of the iliofemoral ligament and the pubocapsular ligament, h a bursa situated on the deep surfaces of the Psoas major and Iliacus.

The **iliofemoral ligament** (fig. 509), triangular in shape and of great ength, lies in front of the joint and is intimately connected with the capsule. a apex is attached to the lower part of the anterior inferior iliac spine, its e to the intertrochanteric line of the femur. The medial and lateral parts the ligament are strong bands, while the central part is relatively thin d weak; the medial band is vertical in direction and is fixed to the lower t of the intertrochanteric line; the lateral band is oblique and is attached the upper part of the same line. The iliofemoral ligament is frequently led the Y-shaped ligament of Bigelow, and its lateral band the *iliotrochanteric ment.*

The **pubocapsular ligament** (fig. 509) is triangular in form with its base the hip-bone, where it is attached to the iliopectineal eminence, the superior rus of the os pubis, the obturator crest and obturator membrane; below, blends with the capsule and with the deep surface of the medial band of the ofemoral ligament.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **ischiocapsular ligament** (fig. 510) has a somewhat spiral di on the back of the joint. From its attachment to the ischium b behind the acetabulum, it is directed upwards and lateralwards over t of the neck of the femur. Some of its fibres are continuous with the zona orbicularis, others are fixed to the base of the greater trochante

The **ligamentum teres femoris** (fig. 511) is a triangular, somewhat band implanted by its apex on the anterosuperior part of the fove femoris; its base is attached by two bands, one into either side of the ac notch, and between these bony attachments it blends with the tr ligament. It is ensheathed by the synovial stratum, and varies g strength in different subjects; occasionally only the synovial stratu and in rare cases even this is absent. The ligament is made tense w thigh is adducted; it is relaxed when the limb is abducted.

FIG. 510.—The right hip-joint. Posterior aspect.

The **glenoidal labrum** (cotyloid ligament) (fig. 503) is a fibrocartil rim attached to the margin of the acetabulum, the cavity of which it de at the same time it protects the edge of the bone, and fills up the ineq of its surface. It bridges over the acetabular notch as the *transverse ace ligament*, and thus forms a complete circle, which closely surrounds th of the femur and assists in holding it in its place. It is triangular on s its base being attached to the margin of the acetabulum, while its op edge is free and sharp. Its surfaces are invested by the synovial stratum internal surface is inclined inwards so as to narrow the acetabulum, and e the cartilaginous surface of the head of the femur. It is much thicker and behind than below and in front.

The **transverse acetabular ligament** (fig. 503) is in reality a p of the glenoidal labrum, though differing from it in having no cartilag among its fibres. It consists of strong, flattened fibres, which cros acetabular notch, and convert it into a foramen through which the n vessels enter the joint.

The *muscles* in relation with the joint are, in front, the Psoas major and I

ated from the capsule by a bursa; above, the rectus and tendon of the Rectus ris and the insertion of Glutæus minimus, the latter being closely adherent e capsule; medially, the Obturator externus and Pectineus; behind, the rmis, Gemellus superior, tendon of Obturator internus, Gemellus inferior, of Obturator externus, and Quadratus femoris (fig. 512).

e arteries supplying the joint are derived from the obturator, medial femoral nflex, and superior and inferior glutæal arteries.

FIG. 511.—The left hip-joint, opened by removing the floor of the acetabulum from within the pelvis.

e nerves are articular branches from the sacral plexus, the sciatic, obturator, ccessory obturator nerves, a branch from the nerve to the quadratus ris, and a filament from the branch of the femoral nerve supplying the us femoris.

Movements.—The movements of the hip-joint are very extensive, and consist xion, extension, adduction, abduction, circumduction, and rotation.

e length of the neck of the femur and its inclination to the body of the bone the effect of converting the angular movements of flexion, extension, adduc- and abduction partially into rotatory movements in the joint. Thus when igh is flexed or extended, the head of the femur, on account of the *medial* ation of the neck, rotates within the acetabulum. The *forward* slope of the similarly affects the movements of adduction and abduction. Conversely on of the thigh, which is permitted by the *upward* inclination of the neck, is simple rotation of the head of the femur in the acetabulum, but is accom- d by a certain amount of gliding.

e hip-joint presents a very striking contrast to the shoulder-joint in the much complete mechanical arrangements for its security and for the limitation of its ments. In the shoulder, as has been seen, the head of the humerus is not ed at all in size to the glenoid cavity, and is hardly restrained in any of its ary movements by the capsule. In the hip-joint, on the contrary, the head of emur is closely fitted to the acetabulum for an area extending over nearly sphere, and at the margin of the bony cup it is still more closely embraced by

Applied Anatomy.—In dislocation of the hip, the head of the thigh-bone may rest at point around its socket' (Bryant); but whatever position it ultimately assumes, primary displacement is generally downwards and medialwards, the capsule giving way at its weakest—that is, its lower and medial—part. The situation subsequently held by the head of the bone is determined by the degree of flexion or extension, and forward or inward rotation of the thigh at the moment of dislocation, influenced, no doubt, by the iliofemoral ligament, which is easily ruptured. When, for instance, the head of the bone is forced backwards, this fulcrum forms a fixed axis, round which the head of the bone rotates, and the latter is driven on the dorsum of the ilium. The iliofemoral ligament also influences the position of the limb in the various dislocations; in the dislocations backwards it is tense, and produces flexion of the limb; in the dislocation on to the pubis, it is relaxed, and therefore allows the external rotator muscles to evert the thigh; and in dislocation into the obturator foramen it is tense, and produces flexion. The muscles attached into the upper part of the femur, with the exception of the Obturator internus, have but little direct influence in determining the position of the head of the bone. Bigelow, however, has endeavoured to show that the obturator internus is the principal agent in dislocating whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium, or in or near the lower sciatic notch; in both dislocations the head passes, in the first instance, in the same direction. But, as Bigelow asserts, in the dislocation on to the dorsum the head of the femur travels up behind the acetabulum, in front of the muscle; while in the dislocation into the lower sciatic notch the head passes behind the muscle, and is prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and therefore remains in the neighbourhood of the pelvis. Bigelow distinguishes these two forms of dislocation by describing them as dislocations backwards, 'above and below' the obturator internus.

FIG. 513.—The right hip-joint, showing the iliofemoral ligament. (After Bigelow.)

The iliofemoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made use of as the fulcrum to a lever, of which the long arm is the body of the femur, and the short arm the neck of the bone (fig. 513).

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep situation and its thick covering of soft parts. Acute inflammation may, and does, frequently occur, and in these cases, when the joint is distended with fluid, the swelling is very easy to detect on account of the thickness of the capsule and the depth of the situation. It is principally to be found on the front of the joint, just medial to the iliofemoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere.

In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case, the limb is flexed, abducted, and rotated outwards. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion; the lateral band of the iliofemoral ligament by abduction; and the medial band of this ligament and the back of the capsule by rotation outwards. It is, therefore, the position of greatest ease. The condition is readily obvious at first, upon examining a patient. If the patient be laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be seen that the pelvis is tilted downwards on the diseased side and the limb apparently longer than its fellow, and that the lumbar portion of the vertebral column is tilted forwards (lordosis). The condition is thus explained: a limb which is flexed and abducted is obviously useless for progression, and in order to overcome the difficulty the patient depresses the affected side of his pelvis, thus producing parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to carry the limb downwards, instead of forwards. In the later stages of the disease the limb becomes flexed and adducted and inverted. This position, at all events as regards adduction, probably results from muscular action and from the patient lying on his

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

sound side. The adductor muscles are supplied by the obturator nerve, and largely supplies the joint. These muscles are therefore thrown into reflex spasm irritation of the peripheral terminations of this nerve in the inflamed articulation.

Congenital dislocation is more commonly met with in the hip-joint than in any articulation. The displacement always takes place on to the dorsum ilii. It is to extreme lordosis, in order to throw the weight of the body backwards.

Excision of the hip may be required for disease or for injury, especially gun may be performed either by an anterior or a posterior incision. The former avoids interference with important structures, especially muscles, than the latter, but of less efficient drainage. In the operation from the front an incision is made about in length, starting immediately below and lateral to the anterior superior spine downwards between the Sartorius and Tensor fasciæ latæ. The interspace between Glutæus minimus and Rectus femoris is then opened, exposing the upper part capsule, which being incised discloses the neck of the bone. The posterior consists in making an incision 8 to 10 cm. long, commencing midway between of the greater trochanter and the iliac crest, and extending down the posterior of the trochanter. The muscles are detached from the greater trochanter, and the opened freely. When there is a possibility of ankylosis occurring, treatment is with the thigh abducted.

IV. THE KNEE-JOINT

The knee-joint is a ginglymus or hinge-joint. It consists of three tions in one: two condyloid joints, one between either condyle of the and the corresponding meniscus and condyle of the tibia; and a third the patella and the femur, partly arthrodial, but not completely so, articular surfaces are not mutually adapted to each other, so that the ment is not a simple gliding one. This view of the construction knee-joint receives confirmation from a study of the articulation in the lower mammals, where, corresponding to these three subdivisions synovial cavities are sometimes found, either entirely distinct or connected together by small communications. This view is further probable by the existence in the middle of the joint of the two ligaments, which may be regarded as the collateral ligaments of the medial lateral joints. The existence of the patellar fold of synovial membrane further indicate a tendency to separation of the synovial cavity into two sacs, one corresponding to the lateral and the other to the medial joint.

The joint is partly subdivided by two menisci (semilunar fibrocartilages) which are placed between the femur and the tibia.

The ligaments of the joint are:

The articular capsule.	Anterior and posterior cruciate.
Ligamentum patellæ.	Transverse.
Oblique and arcuate popliteal.	Coronary.
Tibial and fibular collateral.	

The **articular capsule** (figs. 514, 517) consists of a fibrous stratum is strengthened in almost its entire extent by bands inseparably connected it; above and in front, beneath the tendon of the Quadriceps femoris represented only by the synovial stratum. Its chief strengthening bands derived from the fascia lata and from the tendons surrounding the joint front, expansions from the Vasti and from the fascia lata and its iliotibial fill the intervals between the collateral and anterior ligaments, constitute the *medial and lateral patellar retinacula.* Behind, the capsule consists vertical fibres which arise from the condyles of the femur and tibia and the sides of the inter-condyloid fossa of the femur; the posterior part capsule is therefore situated on the sides of the cruciate ligaments and of them, and they are thus excluded from the joint-cavity. Behind the ligaments is the oblique popliteal ligament which is augmented by fibres from the tendon of the Semimembranosus. Laterally, a prolongation the iliotibial tract fills the interval between the oblique popliteal and the collateral ligaments, and partly covers the latter. Medially, expansions from the Sartorius and Semimembranosus pass upwards to the tibial collateral ligament and strengthen the capsule.

The **synovial stratum** of the knee-joint is the largest in the Commencing at the upper border of the patella, it forms a large beneath the Quadriceps femoris on the lower part of the front of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

514, 522), and usually communicates with a bursa interposed between endon and the front of the femur. The pouch between the Quadriceps front of the femur is supported, during the movements of the knee, by ll muscle, the Articularis genus, which is inserted into it. On either the patella, the synovial stratum extends beneath the aponeuroses Vasti, and more especially beneath that of the Vastus medialis. Below patella it is separated from the ligamentum patellæ by a considerable ity of fat, known as the *infrapatellar pad*. From the medial and lateral ers of the articular surface of the patella, reduplications of the synovial

. 514.—The articular capsule of the right knee-joint (distended). Lateral aspect. (From a specimen prepared by J. C. B. Grant.)

tum project into the interior of the joint. These form two fringe-like folds ed the *alar folds*; below, these folds converge and are continued as a single d the *patellar fold* (ligamentum mucosum), to the front of the intercondyloid of the femur (fig. 515). On either side of the joint, the synovial stratum es downwards from the femur, lining the fibrous stratum of the capsule as far attachment to the menisci; it may then be traced over the upper surfaces these to their free borders, and thence along their under surfaces to the At the back part of the lateral meniscus it forms a cul-de-sac between groove on the surface of the meniscus and the tendon of the Popliteus.

The **ligamentum patellæ** (fig. 517) is the central portion of the common on of the Quadriceps femoris, which is continued from the patella to the rosity of the tibia. It is a strong, flat, ligamentous band, about 8 cm. in gh, attached, above, to the apex and adjoining margins and to the rough ension on the posterior surface of the patella; and below, to the tuberosity the tibia; its superficial fibres are continuous over the front of the patella

The **calcaneofibular ligament** (fig. 527) is a long rounded cord, running from the apex of the fibular malleolus downwards and slightly backwards to a tubercle on the lateral surface of the calcaneus. It is crossed by the tendons of the Peronæi longus et brevis.

The anterior and posterior talofibular and the calcaneofibular ligaments are formerly described as the three fasciculi of the *external lateral ligament* of the ankle-joint.

Relations.—The tendons, vessels, and nerves in relation with the joint are, in front from the medial side; the Tibialis anterior, Extensor hallucis longus, anterior tibial vessels, deep peronæal nerve, Extensor digitorum longus, and Peronæus tertius; behind, from the medial side, the Tibialis posterior, Flexor digitorum longus, posterior tibial vessels, tibial nerve, Flexor hallucis longus; and, in the groove behind the fibular malleolus, the tendons of the Peronæi longus et brevis.

Fig. 527.—The ligaments of the right ankle and tarsus. Lateral aspect.

Dorsal calcaneocuboid ligament

The *arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and from the peronæal.

The *nerves* are derived from the deep peronæal and tibial.

Movements.—When the body is in the erect position, the foot is at right angles to the leg. The movements of the ankle-joint are those of dorsiflexion and extension; dorsiflexion consists in the approximation of the dorsum of the foot to the front of the leg; in extension the heel is drawn up and the toes pointed downwards. The malleoli tightly embrace the talus in all positions of the joint, so that any slight degree of side-to-side movement which may exist is simply due to stretching of the ligaments of the distal talofibular joint, and slight bending of the fibula. The superior articular surface of the talus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight outward rotatory movement of the lower end of the fibula by a stretching of the ligaments of the distal talofibular joint; this lateral movement is facilitated by a slight gliding at the proximal tibiofibular joint, and also by the bending of the body of the fibula. Of the ligaments, the deltoid

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

is of great power—so much so, that it usually resists a force which fra process of bone to which it is attached. Its middle portion, together calcaneofibular ligament, binds the bones of the leg firmly to the foot, a displacement in every direction. Its anterior and posterior fibres limit and flexion of the foot respectively, and the anterior fibres also limit The posterior talofibular ligament assists the calcaneofibular in resisting placement of the foot backwards, and deepens the cavity for the recepti talus. The anterior talofibular ligament is a security against the dis of the foot forwards, and limits extension of the joint.

Muscles producing the movements :

Flexion.—Tibialis anterior, Extensor digitorum longus, Extensor longus, Peronæus tertius.

Extension.—Gastrocnemius, Soleus, Plantaris, Tibialis posterior, digitorum longus, Flexor hallucis longus, Peronæi longus et brevis

Applied Anatomy.—As the ankle-joint is a very strong and powerful articula placement of the talus from the tibiofibular mortise is a rare accident, and grea required to produce it. Nevertheless, dislocation does occasionally occur, either posteriorly or to one or other side. In the latter, which is the more common, is a necessary accompaniment of the injury. The dislocation in these cases is peculiar, and is not a displacement in a horizontal direction, such as usually o dislocations of ginglymoid joints, but the talus undergoes a partial rotation anteroposterior axis drawn through its own centre, so that the superior surface, being directed upwards, is inclined more or less medialwards or lateralwards acc the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and lead to acute synovitis. In these cases, when the synovial sac is distended w the bulging appears principally in the front of the joint, beneath the anterior and on either side, between the Tibialis anterior and the deltoid ligament on th side, and between the Peronæus tertius and the anterior talofibular ligament In addition to this, bulging often occurs posteriorly, and a fluctuating swelling detected on either side of the tendo calcaneus. A large proportion of so-called of the ankle have been proved by *x*-ray examination to be some variety of fractu the malleoli, with or without displacement.

When disease or injury of the ankle-joint is likely to lead to ankylosis, the joi dorsiflexed to rather less than a right angle.

VII. THE INTERTARSAL ARTICULATIONS

1. The Talocalcaneal Articulation

There are two articulations between the calcaneus and talus, an and a posterior; the anterior forms part of the talocalcaneonavicular and will be described with that articulation. The posterior or talocal articulation is formed between the posterior calcaneal facet on the surface of the talus, and the posterior facet on the superior surface calcaneus. It is an arthrodial joint, and the two bones are conne articular capsule and by anterior, posterior, lateral, medial and inter talocalcaneal ligaments.

The **articular capsule** envelops the joint, and consists for the m of short fibres; it is split up into distinct slips, and between these only a weak fibrous investment. It is lined with a synovial stratum, joint-cavity does not communicate with any of the other tarsal joints.

The **anterior talocalcaneal ligament** (fig. 530) extends from the and lateral surfaces of the neck of the talus to the superior surface calcaneus.

The **posterior talocalcaneal ligament** (fig. 526) connects the tubercle on the posterior surface of the talus with the upper and medi of the calcaneus; it is a short band, and its fibres radiate from their attachment to the talus.

The **lateral talocalcaneal ligament** (figs. 524, 527) is a short, fasciculus, passing from the lateral surface of the talus, immediately b its fibular facet, to the lateral surface of the calcaneus. It is placed i of, but on a deeper plane than, the calcaneofibular ligament, with the of which it is parallel.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The medial talocalcaneal ligament connects the medial tubercle on the erior surface of the talus with the back of the sustentaculum tali. Its fibres d with those of the plantar calcaneonavicular ligament.

The interosseous talocalcaneal ligament (figs. 524, 528) is very thick trong, and forms the chief bond of union between the bones. It is, in a portion of the united capsules of the talocalcaneonavicular and the alcaneal joints, and consists of two partially united layers of fibres, one ging to the former and the other to the latter joint. It is attached, w, to the sulcus tali; below, to the sulcus calcanei.

Movements.—The movements permitted between the talus and calcaneus are ed to gliding of the one bone on the other, backwards and forwards and from to side.

Fig. 528.—A coronal section through the right talocrural and talocalcaneal joints.

2. The Talocalcaneonavicular Articulation

This articulation is an arthrodial joint: the rounded head of the talus g received into the concavity formed by the posterior surface of the navi- r bone, the anterior articular surface of the calcaneus, and the upper surface e plantar calcaneonavicular ligament. There are two ligaments in this : the articular capsule and the talonavicular.

The articular capsule is imperfectly developed except posteriorly, where considerably thickened and forms, with a part of the capsule of the talo- neal joint, the strong interosseous ligament which fills the sinus tarsi d by the opposing sulci on the calcaneus and talus, as mentioned above.

The talonavicular ligament (fig. 526) is a broad, thin band, connecting ck of the talus to the dorsal surface of the navicular bone; it is covered the extensor tendons. The plantar calcaneonavicular ligament supplies ace of a plantar ligament for this joint.

Movements.—This articulation permits of a considerable range of gliding ements.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

3. The Calcaneocuboid Articulation

The articular surfaces of the calcaneocuboid joint are somewh shaped. The ligaments of the joint are: the articular capsule, th calcaneocuboid, the calcaneocu tion of the bifurcated ligam long plantar, and the plantar cuboid.

Fig. 529.—The ligaments of the plantar surface of the right foot.

The **articular capsule** certain bands, which form ligaments of the joint. Its stratum is distinct from the other tarsal articulations (fig.

The **dorsal calcaneocub ment** (fig. 527) is a thin b fasciculus, which passes betw contiguous surfaces of the ca and the cuboid bone, on the surface of the joint.

The **bifurcated** ligame 527, 530) is a strong band behind to the deep hollow on th surface of the calcaneus and in front in a **Y**-shaped manne calcaneocuboid and a calca cular part. The *calcaneocub* is fixed to the medial side of the bone and forms one of the bonds between the first and rows of the tarsal bones. The *navicular part* is attached to the side of the navicular bone.

The **long plantar** ligame 529), the longest of the tarsal lig is attached behind to the surface of the calcaneus in front tuberosity, and in front to the tu on the plantar surface of the bone, the more superficial fibre continued forwards to the bases second, third, and fourth me bones. This ligament converts the groove on the plantar surface of the bone into a canal for the tendon of the Peronæus longus.

The **plantar calcaneocuboid ligament** (short plantar ligament) lies nearer to the bones than the preceding, from which it is separate little areolar tissue. It is a short but wide band of great streng extends from the tubercle and the depression in front of it, on the fo of the plantar surface of the calcaneus, to the plantar surface of the bone behind the peronæal groove.

Movements.—The movements permitted between the calcaneus and the bone are limited to slight gliding of the bones upon each other.

The *transverse tarsal joint* is formed by the articulation of the calcaneu the cuboid bone, and the articulation of the talus with the navicular bon movement which takes place in this joint is more extensive than that in th tarsal joints, and consists of a sort of rotation by means of which the foot slightly flexed or extended, the sole being at the same time carried medi (inverted) or lateralwards (everted).

Muscles producing the movements :

Inversion.—Tibialis anterior, Tibialis posterior.

Eversion.—Peronæus longus.

4. The Ligaments connecting the Calcaneus and Navicular

Though the calcaneus and the navicular bone do not directly articulate, are connected by two ligaments: the calcaneonavicular part of the rcated, and the plantar calcaneonavicular.

The calcaneonavicular part of the bifurcated ligament is described p. 426.

The plantar calcaneonavicular ligament (fig. 530) is a broad, thick band necting the anterior margin of the sustentaculum tali of the calcaneus to plantar surface of the navicular bone. This ligament not only unites the aneus with the navi- ar bone, but supports head of the talus, ming part of the arti- ar cavity in which it received. The *dorsal face* of the ligament ents a fibrocartilagi- s facet, lined with the vial stratum, and upon a portion of the head the talus rests. Its *lar surface* is supported the tendon of the alis posterior; its *al border* is blended h the anterior part of deltoid ligament of the le-joint. The plantar aneonavicular and tar calcaneocuboid aments together form *deep ligament* of the ns.

Fig. 530.—The right talocalcaneal and talocalcaneonavicular articulations, exposed by removing the talus. Superior aspect.

pplied Anatomy. — The lar calcaneonavicular liga- t, by supporting the head of talus, is concerned in main- ng the arch of the foot. it yields the head of lus is pressed downwards, medialwards, and forwards by the weight of the body, the foot becomes flattened, expanded, and turned lateralwards, and exhibits the tion known as *flat-foot*. This ligament contains a considerable amount of elastic e, so as to give elasticity to the arch and spring to the foot; hence it is sometimes d the 'spring' ligament. It is supported, on its plantar surface, by the tendon of Tibialis posterior, which spreads out at its insertion into a number of fasciculi, to be ched to most of the tarsal and metatarsal bones. This prevents undue stretching s ligament, and is a protection against the occurrence of flat-foot; hence muscular ess is, in most cases, the primary cause of the deformity.

5. The Cuneonavicular Articulation

The navicular bone is connected to the three cuneiform bones by dorsal and tar ligaments.

The dorsal ligaments are three small fasciculi, one attached to each of the iform bones. The fasciculus connecting the navicular bone with the first iform bone is continuous round the medial side of the articulation with the ar ligament which unites these two bones.

The plantar ligaments have a similar arrangement to the dorsal, and are engthened by slips from the tendon of the Tibialis posterior.

Movements.—Gliding movements are permitted between the navicular and iform bones.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

6. The Cuboideonavicular Articulation

The cuboid bone is connected with the navicular bone by dorsal, p and interosseous ligaments.

The **dorsal ligament** extends obliquely forwards and lateralward the **plantar** passes nearly transversely from the cuboid bone to the n bone

The **interosseous ligament** consists of strong transverse fib connects the rough non-articular portions of the adjacent surfaces of bones.

Movements.—The movements permitted between the navicular and cub are limited to a slight gliding upon each other.

7. The Intercuneiform and Cuneocuboid Articulations

The three cuneiform bones and the cuboid bone are connected toge dorsal, plantar, and interosseous ligaments.

The **dorsal and plantar ligaments** each consist of three transverse one connects the first and second cuneiform bones, another the seco third cuneiform bones, and another the third cuneiform and cuboid The plantar ligaments are strengthened by slips from the tendon of the posterior.

The **interosseous ligaments** connect the rough non-articular por the adjacent surfaces of the bones.

Movements.—The movements permitted between these bones are lim a slight gliding upon each other.

Applied Anatomy.—In spite of the great strength of the ligaments which the tarsal bones together, dislocation at some of the tarsal joints does occasiona When this takes place, it is most commonly in connexion with the talus; for may this bone be dislocated from the tibia and fibula at the ankle-joint, but t bones may be dislocated from it, the talus remaining *in situ* in the tibiofibular This constitutes what is known as the *subtalar* dislocation. Or, again, the talus dislocated from all its connexions—from the tibia and fibula above, the calcaneu and the navicular in front—and may even undergo a rotation, on either a vert horizontal axis. In the former case the long axis of the bone is directed across t so that the head faces the articular surface on one or other malleolus; in the la collateral surfaces are directed upwards and downwards, so that the superior surf to one or the other side. Reduction in these cases is often very difficult or imp and the displaced talus may require removal by open operation. Dislocation m occur at the transverse tarsal joint, the anterior tarsal bones being luxated f talus and calcaneus. The other tarsal bones are occasionally, though rarely, di from their connexions.

The talus is sometimes removed to remedy certain types of club-foot. The in made between the tendons of the Peronæus tertius and Peronæus brevis; the anter posterior talofibular and the calcaneofibular ligaments are divided, and the ank freely opened. In separating the medial side of the talus, the deltoid ligament sheath of the Flexor hallucis longus must be divided close to the bone.

VIII. THE TARSOMETATARSAL ARTICULATIONS

These are arthrodial joints. The first metatarsal bone articulates w first cuneiform bone; the second is deeply wedged in between the f third cuneiform bones, articulating by its base with the second cu bone; the third articulates with the third cuneiform bone; the fourth the cuboid and third cuneiform bones; and the fifth with the cuboid The bones are connected by dorsal, plantar, and interosseous ligaments

The **dorsal ligaments** are strong, flat bands. The first metata joined to the first cuneiform bone by an articular capsule; the seco tarsal receives three bands, one from each cuneiform bone; the thi from the third cuneiform bone; the fourth, one from the third cuneifor and another from the cuboid bone; and the fifth, one from the cuboid b

The **plantar ligaments** consist of longitudinal and oblique bands, d with less regularity than the dorsal ligaments. Those for the first and s

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

tatarsal bones are the strongest; the second and third metatarsal bones are ted by oblique bands to the first cuneiform bone; the fourth and fifth tatarsal bones are connected by a few fibres to the cuboid bone.

The interosseous ligaments are three in number. The first is the strongest passes from the lateral surface of the first cuneiform bone to the adjacent e of the second metatarsal bone. The second connects the third cuneiform e with the adjacent angle of the second metatarsal bone. The third connects lateral angle of the third cuneiform bone with the adjacent side of the of the third metatarsal bone.

Movements.—The movements permitted between the tarsal and metatarsal es are limited to slight gliding of the bones upon each other.

IX. THE INTERMETATARSAL ARTICULATIONS

The base of the first metatarsal bone is not connected with that of the second any ligaments; in this respect the great toe resembles the thumb.

FIG. 531.—An oblique section through the left intertarsal and tarsometatarsal articulations, showing the synovial cavities.

The bases of the second, third, fourth, and fifth metatarsal bones are nected by dorsal, plantar, and interosseous ligaments.

The heads of all the metatarsal bones are connected by the transverse tarsal ligament.

The **dorsal and plantar ligaments** pass transversely between the bases adjacent bones.

The **interosseous ligaments** consist of strong transverse fibres which ect the rough non-articular portions of the adjacent surfaces.

The **transverse metatarsal ligament** is a narrow band which runs across connects together the heads of all the metatarsal bones; it is blended

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

anteriorly with the accessory plantar ligaments of the metatarsopha[illegible] articulations. Its plantar surface is concave where the flexor tend[illegible] below it; above it the tendons of the Interossei pass to their inserti[illegible] differs from the transverse metacarpal ligament in that it connects t[illegible] metatarsal to the others.

Movements.—The movements permitted between the tarsal ends of th[illegible] tarsal bones are limited to a slight gliding of the articular surfaces one upon a[illegible]

The **synovial cavities** (fig. 531) present in the articulations of the [illegible] and metatarsus are six in number: one for the talocalcaneal articulati[illegible] second for the talocalcaneonavicular articulation; a third for the ca[illegible] cuboid articulation; a fourth for the cuneonavicular, intercuneiform[illegible] cuneocuboid articulations, the articulations of the second and third cu[illegible] bones with the bases of the second and third metatarsal bones, and the a[illegible] surfaces of the bases of the second, third, and fourth metatarsal bones; [illegible] for the first cuneiform bone with the metatarsal bone of the great toe; [illegible] sixth, for the articulation of the cuboid bone with the fourth and fifth met[illegible] bones. A small synovial cavity is sometimes found between the con[illegible] surfaces of the navicular and cuboid bones; it may communicate wit[illegible] between the cuboid and third cuneiform bones.

X. THE METATARSOPHALANGEAL ARTICULATIONS

The metatarsophalangeal articulations are of the condyloid kind, [illegible] by the reception of the rounded heads of the metatarsal bones in [illegible] cavities on the bases of the first phalanges.

The ligaments are the accessory plantar and collateral.

The **accessory plantar ligaments** (glenoid ligaments of Cruveilhi[illegible] thick, dense, fibrous structures. They are placed on the plantar surf[illegible] the joints in the intervals between the collateral ligaments, to which th[illegible] connected; they are loosely united to the metatarsal bones, but are [illegible] fixed to the bases of the first phalanges. Their plantar surfaces are intim[illegible] blended with the transverse metatarsal ligament, and grooved for the [illegible] tendons, the fibrous sheaths of which are connected to the sides o[illegible] grooves; the deep surfaces of the ligaments form parts of the articular [illegible] for the heads of the metatarsal bones.

The **collateral ligaments** are two strong, rounded cords, placed o[illegible] sides of the joints; each is attached by one end to the posterior tuber[illegible] the side of the head of the metatarsal bone, and by the other to the [illegible] sponding side of the base of the phalanx.

The place of *dorsal ligaments* is supplied by the extensor tendons o[illegible] dorsal surfaces of the joints.

Movements.—The movements permitted in the metatarsophalangeal ar[illegible] tions are flexion, extension, adduction, abduction and circumduction.

Muscles producing the movements:

Flexion.—Flexores digitorum longus et brevis, Quadratus plantæ, Lumb[illegible] Interossei dorsales et plantares, Flexores hallucis longus et brevis, [illegible] digiti quinti proprius.

Extension.—Extensores digitorum longus et brevis, Extensor hallucis l[illegible]

Adduction.—Interossei plantares, Adductor hallucis, long flexors of toes.

Abduction.—Interossei dorsales, Abductor hallucis, Abductor digiti q[illegible]

XI. THE ARTICULATIONS OF THE DIGITS

The interphalangeal articulations are hinge-joints, and each has a plant[illegible] two collateral ligaments.

The arrangement of these ligaments is similar to that in the metatarsopha[illegible] articulations: the extensor tendons supply the places of dorsal ligaments.

Movements.—The only movements permitted in the joints of the digi[illegible] flexion and extension; these movements are more extensive between the fir[illegible] second phalanges than between the second and third. The amount of flexion i[illegible] considerable, but extension is limited by the accessory plantar ligaments.

CC-0.In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Muscles producing the movements:

Flexion.—Flexores digitorum longus et brevis, Quadratus plantæ, Flexor hallucis longus.

Extension.—Lumbricales, Interossei dorsales et plantares, Extensor hallucis longus, Extensores digitorum longus et brevis.

Applied Anatomy.—When the head of the first metatarsal bone is removed for the disease which occurs in chronic arthritis, the sesamoid bones in the Flexor hallucis tendon should not be removed, since they form a protection to the new joint. The bursa over the head of the metatarsal bone is used in this operation to make the new joint-cavity.

The Arches of the Foot

In order that the foot may support the weight of the body in the erect posture with the least expenditure of material, it is constructed of a series of arches formed by the tarsal and metatarsal bones, and strengthened by the ligaments, tendons and muscles of the foot.

The main arches are the anteroposterior arches, which may be regarded as divisible into two types—a medial and a lateral.

Fig. 532.—The skeleton of the left foot. Medial aspect.

Fig. 533.—The skeleton of the left foot. Lateral aspect.

The *medial arch* (fig. 532) is made up by the calcaneus, the talus, the navicular, the three cuneiform, and the first, second, and third metatarsal bones. Its summit is the superior articular surface of the talus, and its two extremities or piers, on which it rests in standing, are the tuberosity on the plantar surface of the calcaneus posteriorly, and the heads of the first, second, and third metatarsal bones anteriorly. The chief characteristic of this arch is its elasticity, due to its height and to the number of joints between its component parts. Its weakest part, the part most liable to yield from over-pressure, is the joint between the talus and the navicular bone, but this is braced by the plantar calcaneonavicular ligament, which is elastic and is thus able quickly to restore the arch when the disturbing force is removed. This ligament is strengthened medially by blending with the deltoid ligament of the ankle-joint, and is supported inferiorly by the tendon of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the Tibialis posterior. The arch is further supported by the plantar a
by the small muscles in the sole of the foot, by the tendon of the Tibialis
and by the ligaments of all the articulations involved.

The *lateral arch* (fig. 533) is composed of the calcaneus, the cuboid,
fourth and fifth metatarsal bones. Its summit is at the talocalcaneal art
and its chief joint is the calcaneocuboid, which possesses a special mech
locking, and allows only a limited movement. The most marked feature
arch are its solidity and its slight elevation; two strong ligaments, the lon
and the plantar calcaneocuboid, the tendon of the Peronæus longus, the
tendons, and the short muscles of the little toe, preserve its integrity.

In addition to the longitudinal arches the foot presents a series of tr
arches. At the posterior part of the metatarsus and the anterior part of th
the arches are complete, but in the middle of the tarsus they present
characters of half-domes the concavities of which are directed downwa
medialwards, so that when the medial borders of the feet are placed in a
a complete tarsal dome is formed. The transverse arches are strengthened
interosseous, plantar, and dorsal ligaments, by the short muscles of the first
toes (especially the transverse head of the Adductor hallucis), and by the P
longus, the tendon of which stretches between the piers of the arches.

Applied Anatomy.—Pes planus or flat-foot is a very common deformity d
disappearance of the arches of the foot, from subsidence dependent on stretchi
plantar ligaments. In its early stages before the deformity is marked it is acco
by considerable pain from pressure on the plantar nerves, but when the condition
formed and the head of the talus has descended completely, the condition is pai
irremediable.

The stretching of the ligaments in this condition is most often due to muscu
ness in young adults who may have to stand for long periods daily. The deep
especially the posterior tibial group, by their tonicity are the most potent in ma
the longitudinal arch, and when overtired they relax and throw the strain on the
ligaments which yield secondarily. All three posterior tibial muscles are eff
thus supporting the longitudinal arch, but perhaps the most important one is the
hallucis longus which normally stretches like a bow-string across the whole
posterior length of the arch.

The transverse arch subsequently disappears, this having been largely held up
Peronæus longus. In the treatment of this static form of flat-foot, muscular
essential in the early stages, as once the ligamentous tissues are stretched, t
unable to return to their original condition.

There are, however, other forms of flat-foot, viz. the congenital, and the p
(due to affections of the nerve-centres supplying the post-tibial group of muscles
due to inflammation of the tarsal joints and those following injuries to the tar
metatarsus. If in the two later forms the patient put his weight on the foot be
normal condition has been fully established, pes planus is certain to result, a
arches will not be capable of restoration subsequently.

Pes cavus, the opposite of pes planus, is usually due to some contracture
posterior tibial group in certain affections of the medulla spinalis. It is also co
seen in association with talipes equinus or equinovarus, and here the longitudinal
of the foot is greatly increased, with contraction of the plantar aponeurosis which
instances becomes very pronounced.

MYOLOGY*

HE muscles are connected with the bones, cartilages, ligaments, and skin, either directly, or through the intervention of fibrous structures called ons or aponeuroses. Where a muscle is attached to bone or cartilage, the s end in blunt extremities upon the periosteum or perichondrium, and do come into direct relation with the osseous or cartilaginous tissue. Where les are connected with the skin, they lie as a flattened layer beneath it, and nited with its areolar tissue by larger or smaller bundles of fibres.

Muscles vary in their form. In the limbs, they are of considerable length, ecially the more superficial ones; they surround the bones, and constitute important protection to the joints. In the trunk, they are broad and tened, and assist in forming the walls of the trunk cavities. Hence the ion of the terms, *long, broad, short*, &c., used in the description of muscles.

There is considerable variation in the arrangement of the fibres of certain cles with reference to the tendons to which they are attached. In some cles the fibres are parallel and run directly from their origin to their ertion; these are quadrilateral muscles, such as the Thyreohyoideus. A dification of these is found in the fusiform muscles, in which the fibres are quite parallel, but slightly curved, so that the muscle tapers at either end; their mode of action, however, they resemble the quadrilateral muscles. ther muscles the fibres arise by a broad origin and converge to a narrow or ted insertion; this arrangement is found in the triangular muscles—e.g. Temporalis. In some muscles, which otherwise would belong to the drilateral or triangular type, the origin and insertion are not in the same ne, the plane of the line of origin intersecting that of the line of insertion: h is the case in the Pectineus. In some muscles (e.g. the Peronæi) the fibres oblique and are attached to one side of a tendon; such muscles are termed nnate. A modification of this condition is found where oblique fibres ired to both sides of a central tendon; such muscles are called bipennate, an example is afforded in the Rectus femoris. Finally, there are muscles hich the fibres are arranged in curved bundles in one or more planes, as in Sphincters. The arrangement of the fibres is of considerable importance respect to the relative strength and range of movement of the muscle. Those scles where the fibres are long and few in number have great range, but minished strength; where, on the other hand, the fibres are short and more merous, there is great power, but lessened range.

The names applied to the various muscles have been derived: 1, from their ation, as the Tibialis anterior, Tibialis posterior; 2, from their direction, as the ms abdominis, Obliqui capitis, Transversus abdominis; 3, from their uses, Flexors, Extensors, Abductors, &c.; 4, from their shape, as the Deltoideus, mboideus; 5, from the number of their divisions, as the Biceps, and Triceps; from their attachment, as the Sternocleidomastoideus, Sternohyoideus, rnothyreoideus.

* The muscles and fasciæ are described conjointly, in order that the student may consider arrangement of the latter in his dissection of the former. It is rare for the student of anatomy ose country to have the opportunity of dissecting the fasciæ separately; and it is for this son, as well as from the close connexion that exists between the muscles and their investing ia, that they are considered together. Some general observations are first made on the ny of the muscles and fasciæ, the special descriptions being given in connexion with the ent regions.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In the description of a muscle, the term *origin* is meant to imply its m or central attachment; and the term *insertion* the movable point to w force of the muscle is applied; but the origin is absolutely fixed in only number of muscles, such as those of the face which are attached by one immovable bones, and by the other to the movable skin. Most of the mu be made to act from either end.

In the dissection of the muscles, attention should be directed to the origi *tion*, and *actions* of each, and to their more important *relations* with sur parts. While accurate knowledge of the points of attachment of the mus great importance in determining their actions, it is not to be regarded as co The action of the muscle deduced from its attachments, or even by pulling the dead subject, is not necessarily its action in the living. By pulling, for on the Brachioradialis in the cadaver the hand may be slightly supinated the prone position and slightly pronated when in the supine position, but th evidence that these actions are performed by the muscle during life. It is im for an individual to throw into action any one muscle; in other words, mov not muscles, are represented in the central nervous system. To carry out ment a definite combination of muscles is called into play, and the individ no power either to leave out a muscle from this combination, or to add one One (or more) muscle of the combination is the chief moving force; wh muscle passes over more than one joint, other muscles (synergic muscles) co play to inhibit the movements not required; a third set of muscles (fixation m fix the limb—i.e. in the case of the limb-movements—and also prevent distu of the equilibrium of the body generally. As an example, the movement closing of the fist may be considered: (1) the prime movers are the Flexor torum, Flexor pollicis longus, and the small muscles of the thumb; (2) the s muscles are the Extensores carpi, which prevent flexion of the wrist; while fixation muscles are the Biceps and Triceps brachii, which steady the elb shoulder. A further point which must be borne in mind in considering the of muscles is that in certain positions a movement can be effected by grav in such a case the muscles acting are the antagonists of those which m supposed to be in action. Thus in flexing the trunk when no resistance is im the Sacrospinales contract to regulate the action of gravity, and the Recti ab are relaxed.*

The minute anatomy of muscular tissue is described on pp. 29 to 33.

Applied Anatomy.—By a consideration of the actions of the muscles, the su able to explain the causes of displacement in various forms of fracture, and the which produce distortion in various deformities, and, consequently, to adopt appr treatment in each case. The relations, also, of some of the muscles, especially t immediate apposition with the large blood-vessels, and the surface markings they p should be remembered, as they form useful guides in the application of ligatures to vessels. Degeneration of muscular tissue is important clinically, and is met with i main conditions. In one, the degeneration is myopathic, or primary in the muscles selves; in the other it is neuropathic, or secondary to some lesion of the nervous sys a hæmorrhage into the brain, for example, or injury or inflammation of some part medulla spinalis or peripheral nerves. In either case more or less paralysis and of the affected muscles result. When the degeneration begins primarily in the m however, it often happens that though the muscle-fibres waste away, their place is by fibrous and fatty tissue to such an extent that the affected muscles increase in and actually appear to hypertrophy.

Ossification of muscular tissue as a result of repeated strain or injury is not infr It is oftenest found about the tendon of the Adductor longus in horsemen, in the Pe major and Deltoideus of soldiers, or in the tendon of the Brachialis after dislocation elbow. It may take the form of exostoses firmly fixed to the bone—e.g. 'rider's on the femur—or of layers or spicules of bone lying in the muscles or their fascia tendons. Busse states that these bony deposits are preceded by a hæmorrhagic m due to injury, the effused blood organising and being finally converted into bone. rarer disease, progressive myositis ossificans, there is an unexplained tendency for cally any of the voluntary muscles to become converted into solid and brittle bony which are completely rigid.

THE TENDONS, APONEUROSES, AND FASCIÆ

e tendons are white, glistening cords, varying in length and thickness, evoid of elasticity. They consist almost entirely of white fibrous tissue, ibrils of which have an undulating course parallel with each other and are y united together. They are very sparingly supplied with blood-vessels, smaller tendons presenting in their interior no trace of them. Nerves ying tendons end in what are known as neurotendinous spindles or organs lgi; these are described with the organs of the senses.

he aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white r, iridescent and glistening; they are only sparingly supplied with blood-

he tendons and aponeuroses connect the muscles with the movable struc- s, such as the bones and cartilages. Where the end of a muscle is continued ly into a tendon, the line of junction between the two is usually well- ed, but where the muscle meets the tendon obliquely, bundles of tendon s generally run for a variable distance into the substance of the muscle, t the line of junction is irregular. Microscopic examination shows that, er case, the tendon is subdivided into small bundles, corresponding in nd number with the fibres of the muscle. Each muscular fibre ends more or less rounded extremity covered by sarcolemma, and the fibres of tendon bundle are intimately united with the sarcolemma covering the of the muscular fibre. The mode of union is well shown when the muscle has shrunk inside its sarcolemma.

he fasciæ are fibro-areolar or aponeurotic laminæ, of variable thickness strength, found in all regions of the body, investing the softer and more ate organs. During the process of development many of the cells of the oderm are differentiated into bones, muscles, vessels, &c.; the cells of esoderm which are not so utilised form an investment for these structures are differentiated into the true skin and the fasciæ of the body. The e are subdivided into superficial and deep.

he *superficial fascia* is found immediately beneath the integument over st the entire surface of the body. It connects the skin to the subjacent , and consists of fibro-areolar tissue, containing in its meshes pellicles t in varying quantity. It varies in thickness in different parts of the ; in the groin it is so thick that it may be subdivided into several laminæ. ith the fatty layer there is generally another layer of superficial fascia, st devoid of adipose tissue, in which the trunks of the subcutaneous vessels nerves and the superficial lymph-glands are found. Certain cutaneous s are situated in the superficial fascia, e.g. the Platysma and the muscles e face. The superficial fascia is most distinct at the lower part of the men, perinæum, and extremities; it is very thin in those regions where ular fibres are inserted into the integument, as on the side of the neck, e face, and around the anus. It is very dense in the scalp, palms of the , and soles of the feet, forming a fibrofatty layer, which binds the integu- firmly to the underlying structures. It facilitates the movement of kin, serves as a soft nidus for the passage of vessels and nerves to the , and retains the warmth of the body, since the fat contained in its areolæ bad conductor of heat.

he *deep fascia* is a dense, inelastic membrane, forming sheaths for the les, and in some cases affording them broad surfaces for attachment. consists of shining tendinous fibres, placed parallel with one another, and ected together by other fibres disposed in a rectilinear manner. It forms ing investment which not only binds down collectively the muscles in each n, but gives a separate sheath to each, as well as to the vessels and nerves. sists the muscles in their actions by the degree of tension and pressure kes upon their surfaces; in certain situations the degree of tension and ure is regulated by muscles, as, for instance, by the Tensor fasciæ latæ Glutæus maximus in the thigh, and the Palmaris longus in the hand. In limbs, the fascia not only invests the limb, but gives off septa which separate various muscles, and are attached to the periosteum; these prolongations asciæ are usually spoken of as intermuscular septa.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

The fasciæ and muscles may be grouped into those of the head and of the trunk; of the upper extremity; and of the lower extremity.

THE FASCIA AND MUSCLES OF THE HEAD

I. The Muscle of the Scalp

Epicranius

The **superficial fascia** in the cranial region is a firm, fibrofatty, intimately adherent to the integument, and to the Epicranius and its tendinous aponeurosis; behind, it is continuous with the superficial fascia at the back of the neck; laterally, is prolonged over the temporal fascia.

Fig. 534.—The muscles of the scalp and face. Left lateral aspect.

The **Epicranius** (Occipito-frontalis) (fig. 534) is a broad, musculofibrous layer, which covers the vertex of the skull on either side, from the occiput

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to the eyebrow. It consists of two parts, the Occipitalis and the Frontalis, ected by an intervening aponeurosis, the galea aponeurotica.

The *Occipitalis*, thin and quadrilateral in form, arises by tendinous fibres the lateral two-thirds of the highest nuchal line of the occipital bone, and the mastoid part of the temporal bone. It ends in the galea aponeurotica.

The *Frontalis* is thin, of a quadrilateral form, and intimately adherent to the ficial fascia. It is broader than the Occipitalis and its fibres are longer and in colour. It has no bony attachments. Its medial fibres are continuous those of the Procerus; its intermediate fibres blend with the Corrugator Orbicularis oculi; and its lateral fibres are also blended with the latter o over the zygomatic process of the frontal bone. From these attachments bres are directed upwards, and join the galea aponeurotica in front of the al suture. The medial margins of the Frontales are joined together for distance above the root of the nose; but between the Occipitales there is considerable, though variable, interval, occupied by the galea aponeurotica.

The **galea aponeurotica** (epicranial aponeurosis) covers the upper part e cranium; behind, it is attached, in the interval between the Occipitales, e external occipital protuberance and highest nuchal line of the occipital ; in front, it forms a short and narrow prolongation between the Frontales. ther side it gives origin to the Auriculares anterior et superior; in this ion it loses its aponeurotic character, and is continued over the temporal to the zygomatic arch. It is closely united to the integument by the fibrofatty superficial fascia: it is connected to the pericranium by loose ar tissue, which allows of the movement of the aponeurosis, the latter ying with it the integument.

Nerve-supply.—The Occipitalis is supplied by the posterior auricular branch, and Frontalis by the temporal branches, of the facial nerve.

Actions.—The Occipitales draw the scalp backwards; the Frontales acting from e raise the eyebrows and the skin over the root of the nose; acting from below draw the scalp forwards, throwing the integument of the forehead into trans- wrinkles. By bringing alternately into action the Occipitales and Frontales ire scalp may be moved backwards and forwards. In the ordinary action e Frontales, the eyebrows are elevated, thus giving to the face the expression rprise: if the action be exaggerated, the eyebrows are still further raised, and kin of the forehead thrown into transverse wrinkles, as in the expression of t or horror.

A thin muscular slip, the *Transversus nuchæ*, is present in about 25 per cent. of s; it arises from the external occipital protuberance or from the superior nuchal either superficial or deep to the Trapezius; it is frequently inserted with the icularis posterior, but may join the posterior edge of the Sternocleidomastoideus.

plied Anatomy.—The scalp consists of five layers, viz. the skin, subcutaneous e, Epicranius and its aponeurosis, subaponeurotic connective tissue, and peri- um. But from a surgical standpoint it is better to regard the first three of these as ngle layer, since they are all intimately fused together, and when torn off in an ant, or turned down as a flap in a surgical operation, remain firmly connected to other. In consequence of the dense character of the subcutaneous tissue, the nt of swelling which occurs as the result of inflammation is slight; and the edges wound which does not involve the Epicranius or its aponeurosis do not gape. The d-vessels, also, which lie in this tissue, when wounded, do not contract and retract ly; and therefore the hæmorrhage from scalp wounds is often very considerable, but always be arrested by pressure—a matter of great importance, as it is often very lt or impossible to pick up with forceps a wounded vessel in the scalp.

The subaponeurotic connective tissue is, from a surgical point of view, of considerable portance. It is loose and lax, and is easily torn through; and hence, when the scalp wounded, this is the tissue which is torn when the flap is separated from the parts eath. The vessels are contained in the flap, and there is little risk of sloughing, ss the vitality of the part has been actually destroyed by the injury. In consequence e loose nature of the subaponeurotic tissue, any septic inflammation is apt to assume ry diffuse form and spread over the skull, and, unless relieved by timely incisions, lead to serious complications. Owing to the attachments of the aponeurosis to the matic arch and highest nuchal line, subaponeurotic effusions sag down in these ations, but do not extend beyond to the infratemporal fossa, or into the neck; ticularly, however, where there is no definite attachment to bone, the effusion will pass s over the nose, and into the eyelids. When making incisions into the scalp, care uld be taken to avoid the course of the temporal vessels.

II. The Muscles of the Eyelids

Levator palpebræ superioris. Orbicularis oculi.

The Levator palpebræ superioris is described with the anatomy of the orbit.

The **Orbicularis oculi** (figs. 534, 535) is a broad, flat, elliptical muscle which occupies the eyelids or palpebræ, surrounds the circumference of the orbit, spreads over the temporal region, and downwards on the cheek, and consists of three main portions, orbital, palpebral and lacrimal.

Fig. 535.—The left Orbicularis oculi. Posterior aspect.

The *orbital portion* of the Orbicularis oculi, of a reddish colour and thicker than the palpebral portion, arises from the nasal part of the frontal bone, from the frontal process of the maxilla (fig. 536), and from the medial palpebral ligament (tendo oculi) which interrupts the line of the bony origin. Its fibres form complete ellipses without interruption on the lateral side, the upper part blending with the Frontalis and Corrugator.

The *palpebral portion* of the Orbicularis oculi is thin and pale; it arises from the medial palpebral ligament, chiefly from its superficial and partly from its deep surface, but not from its lower margin; it also arises from the bone immediately above and below the ligament. The muscular fibres sweep over the eyelids in front of the orbital septum, and at the lateral commissure they lace to form the lateral palpebral raphe. A small bundle of very fine fibres lies close to the margin of each eyelid, behind the eyelashes; it is called the *ciliary bundle* or muscle of Riolan.

The *lacrimal portion* of the Orbicularis oculi (Tensor tarsi) lies behind the lacrimal sac. It arises from the fascia covering the lacrimal sac, from the upper part of the posterior lacrimal crest, and the adjacent part of the bone surface of the lacrimal bone. Passing lateralwards behind the lacrimal sac the muscle divides into two slips, an upper and a lower; some of the fibres of these slips are inserted into the superior and inferior tarsi and are also related to the lacrimal ducts, but most of them are continued across the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

front of the tarsal plates (*pars tarsalis*) and interlace in the lateral palpebral line.

The *medial palpebral ligament* (tendo oculi), about 4 mm. in length and 2 mm. in breadth, is attached to the frontal process of the maxilla in front of the lacrimal groove. Crossing the lacrimal sac, it divides into two parts, upper and lower, each attached to the medial end of the corresponding tarsus. As the ligament crosses the lacrimal sac, an aponeurotic lamina is given off from the posterior surface; this expands over the sac, and is attached to the posterior lacrimal crest.

The *lateral palpebral raphe* is a much weaker structure than the medial palpebral ligament. It is formed by the interlacing of the lateral ends of the palpebral fibres of the Orbicularis oculi, strengthened on its deep surface by the orbital septum. It passes over the orbital margin, and is attached to the bone by connective tissue only (Whitnall).

Nerve-supply.—The Orbicularis oculi is supplied by the temporal and zygomatic branches of the facial nerve.

Actions.—The Orbicularis oculi is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbital portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn towards the medial angle of the orbit, and the eyelids are firmly closed. The skin thus drawn upon is drawn into folds, especially radiating from the lateral angle of the eyelids; these folds become permanent in old age, and form the so-called 'crow's feet.' The levator palpebræ superioris is the direct antagonist of this muscle since it raises the upper eyelid and exposes the front of the bulb of the eye. The lacrimal part of the Orbicularis oculi draws the eyelids and the papillæ lacrimales medialwards, and directs them into the lacus lacrimalis; it also dilates the lacrimal sac.

Fig. 536.—A sketch showing the attachments of the muscles around the base of the orbit.

The **Corrugator** is a small pyramidal muscle, placed at the medial end of the eyebrow, beneath the Frontalis and Orbicularis oculi. It arises from the medial end of the superciliary arch; and its fibres pass lateralwards and slightly upwards, and are inserted into the deep surface of the skin, above the middle of the orbital arch.

Nerve-supply.—The Corrugator is supplied by the temporal branches of the facial nerve.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Actions.—The Corrugator draws the eyebrow medialwards and downwards, producing the vertical wrinkles of the forehead. It is the 'frowning' muscle, and may be regarded as the principal muscle in the expression of suffering.

III. The Muscles of the Nose (fig. 534)

Procerus.	Depressor septi.
Nasalis.	Dilatator naris posterior.

Dilatator naris anterior.

The **Procerus** (Pyramidalis nasi) is a small pyramidal slip arising by tendinous fibres from the fascia covering the lower part of the nasal bone and the upper part of the lateral nasal cartilage; it is inserted into the skin of the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Frontalis.

Nerve-supply.—The Procerus is supplied by the buccal branches of the facial nerve.

Actions.—The Procerus draws down the medial angle of the eyebrow and produces the transverse wrinkles over the bridge of the nose.

The **Nasalis** (Compressor naris) consists of two parts, transverse and alar. The *transverse part* arises from the maxilla, above and lateral to the incisive fossa; its fibres proceed upwards and medialwards, expanding into an aponeurosis which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Procerus. The *alar part* is attached by one end to the greater alar cartilage, and by the other to the integument at the apex of the nose.

Nerve-supply.—The Nasalis is supplied by the buccal branches of the facial nerve.

Actions.—The Nasalis depresses the cartilaginous part of the nose, and draws the ala towards the septum.

The **Depressor septi** arises from the incisive fossa of the maxilla; it ascends to be inserted into the septum and back part of the ala of the nose. It lies between the mucous membrane and muscular structure of the lip.

Nerve-supply.—The Depressor septi is supplied by the buccal branches of the facial nerve.

Actions.—The Depressor septi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downwards and thereby constricting the aperture of the naris.

The **Dilatator naris posterior** is placed partly beneath the Quadratus labii superioris. It arises from the margin of the nasal notch of the maxilla and from the lesser alar cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a delicate fasciculus, passing from the greater alar cartilage to the integument near the margin of the nostril, and situated in front of the preceding.

Nerve-supply.—The Dilatatores naris, posterior et anterior, are supplied by the buccal branches of the facial nerve.

Actions.—The Dilatatores enlarge the apertures of the nares. Their action in ordinary breathing is to resist the tendency of the nares to close from atmospheric pressure, but in difficult breathing, as well as in some emotions, such as anger, they contract strongly.

IV. The Muscles of the Mouth (fig. 534)

Quadratus labii superioris.	Quadratus labii inferioris.
Caninus.	Triangularis.
Zygomaticus.	Buccinator.
Mentalis.	Orbicularis oris.

Risorius.

The **Quadratus labii superioris** is a broad sheet, the origin of which extends from the side of the nose to the zygomatic bone. Its medial

m the *angular head*, which arises by a pointed extremity from the upper e of the frontal process of the maxilla, and passing obliquely downwards lateralwards divides into two slips. One of these is inserted into the er alar cartilage and skin of the nose; the other is prolonged into the l part of the upper lip, blending with the infra-orbital head and with Orbicularis oris. The intermediate portion or *infra-orbital head* arises m the lower margin of the orbit immediately above the infra-orbital foramen, e of its fibres arising from the maxilla, others from the zygomatic bone. fibres converge, to be inserted into the muscular substance of the upper between the angular head and the Caninus. The lateral fibres form the matic *head*, and are separated from the rest of the muscle by a narrow rval; they arise from the malar surface of the zygomatic bone immediately nd the zygomaticomaxillary suture and pass downwards and medialwards e upper lip.

Nerve-supply.—The Quadratus labii superioris is supplied by the buccal branches e facial nerve.

Actions.—The Quadratus labii superioris raises the upper lip and at the same everts it. Its angular head also acts as a dilator of the naris; the infra-orbital zygomatic heads assist in forming the nasolabial furrow, which passes from le of the nose to the upper lip and gives to the face an expression of sadness. the whole muscle is in action it gives to the countenance the expression of mpt and disdain.

The Caninus (Levator anguli oris) arises from the canine fossa, immediately w the infra-orbital foramen; its fibres are inserted into the angle of mouth, intermingling with those of the Zygomaticus, Triangularis, and bularis oris.

Nerve-supply.—The Caninus is supplied by the buccal branches of the facial nerve.

Actions.—The Caninus raises the angle of the mouth and assists in producing the abial furrow.

The Zygomaticus arises from the zygomatic bone, in front of the zygo- ootemporal suture, and descending obliquely with a medial inclination, serted into the angle of the mouth, where it blends with the fibres of the inus, Orbicularis oris, and Triangularis.

Nerve-supply.—The Zygomaticus is supplied by the buccal branches of the facial e.

Actions.—The Zygomaticus draws the angle of the mouth upwards and lateral- ds as in laughing.

The Mentalis (Levator menti) is a conical fasciculus, situated at the side e frenulum of the lower lip. It arises from the incisive fossa of the mandible descends to be inserted into the integument of the chin.

Nerve-supply.—The Mentalis is supplied by the mandibular branch of the facial e.

Actions.—The Mentalis raises and protrudes the lower lip, and at the same time ldles the skin of the chin, expressing doubt or disdain.

The Quadratus labii inferioris is a quadrilateral muscle. It arises m the oblique line of the mandible, between the symphysis and the mental men, and passes upwards and medialwards, to be inserted into the integu- t of the lower lip, its fibres blending with the Orbicularis oris, and with e of its fellow of the opposite side. At its origin it is continuous with the s of the Platysma. Much yellow fat is intermingled with the fibres of muscle.

Nerve-supply.—The Quadratus labii inferioris is supplied by the mandibular ch of the facial nerve.

Actions.—The Quadratus labii inferioris draws the lower lip downwards and a lateralwards, as in the expression of irony.

The Triangularis (Depressor anguli oris) arises from the oblique line of the dible below and lateral to the Quadratus labii inferioris; its fibres converge are inserted by a narrow fasciculus into the angle of the mouth. At rigin it is continuous with the Platysma, and at its insertion with the icularis oris and Risorius; some of its fibres are directly continuous with e of the Caninus, and others are occasionally found crossing from the le of one side to that of the other; these latter fibres constitute the *nverserus menti*.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Nerve-supply.—The Triangularis is supplied by the mandibular branch of the facial nerve.

Actions.—The Triangularis draws the angle of the mouth downwards and lateralwards.

The **Buccinator** (fig. 537) is a thin quadrilateral muscle, occupying the interval between the maxilla and the mandible, at the side of the face.

FIG. 537.—The Buccinator and the muscles of the pharynx.

from the outer surfaces of the alveolar processes of the maxilla and mandible opposite to the three molar teeth; and behind, from the anterior border of the pterygomandibular raphe which separates the muscle from the Constrictor pharyngis superior. The fibres converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the lower segment; the highest and lowest fibres are continued forward to the corresponding lip without decussation.

labii inferioris) on either side of the middle line; this slip arises from the mandible, lateral to the Mentalis, and intermingles with the other muscles at the angle of the mouth.

Nerve-supply.—The Orbicularis oris is supplied by the buccal and mandibular branches of the facial nerve.

Actions.—The Orbicularis oris in its ordinary action effects the direct closure of the lips; by its deep, assisted by its oblique, fibres, it compresses the lips against the teeth. The superficial part, consisting principally of the decussating fibres, brings the lips together and protrudes them.

The **Risorius** arises from the parotideomasseteric fascia and is inserted into the skin at the angle of the mouth (fig. 534). It is a narrow band of fibres, broadest at its origin, but varying much in its size and form.

Nerve-supply.—The Risorius is supplied by the buccal branches of the facial nerve.

Actions.—The Risorius retracts the angle of the mouth, and produces a pleasant grinning expression.

V. The Muscles of Mastication

Masseter.	Pterygoideus externus.
Temporalis.	Pterygoideus internus.

Covering the Masseter, and firmly connected with it, is a strong layer of fascia derived from the fascia colli and named the **parotideomasseteric fascia**. It is attached to the lower border of the zygomatic arch, and invests the parotid gland (p. 448).

The **Masseter** (fig. 534) is a quadrilateral muscle, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a strong aponeurosis from the zygomatic process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch; its fibres pass downwards and backwards, to be inserted into the angle and lower one-half of the lateral surface of the ramus of the mandible. The *deep portion* is much smaller and is partly concealed by the superficial portion; it arises from the posterior one-third of the lower border and from the whole of the medial surface of the zygomatic arch; its fibres pass downwards and forwards, to be inserted into the lateral surfaces of the coronoid process and the upper one-half of the ramus of the mandible.

Relations.—*Superficial* to the muscle are the integument, the Platysma, the Risorius, the Zygomaticus, and the parotid gland; the parotid duct, branches of the facial nerve, and the transverse facial vessels cross the muscle. The *deep surface* is in relation with the insertion of the Temporalis and the ramus of the mandible; a mass of fat separates it from the Buccinator muscle and nerve. The masseteric nerve and artery enter the muscle on its deep surface. The *posterior margin* is overlapped by the parotid gland; the *anterior margin* projects over the Buccinator and is crossed below by the anterior facial vein.

Nerve-supply.—The Masseter is supplied by the masseteric branch of the anterior trunk of the mandibular nerve.

Actions.—The Masseter pulls the mandible towards and against the maxilla; from its relation to the axis of movement it can act with very great force.

The **temporal fascia** covers the Temporalis. It is a strong, fibrous investment, covered, laterally, by the Auriculares anterior et superior, the galea aponeurotica, and a part of the Orbicularis oculi. The superficial temporal vessels and the auriculotemporal nerve cross it from below upwards. Above it is a single layer, attached to the entire extent of the superior temporal line; below, it consists of two layers, one of which is attached to the lateral, the other to the medial border of the zygomatic arch. A small quantity of fat, the zygomatico-orbital branch of the superficial temporal artery, and the zygomaticotemporal branch of the maxillary nerve, are contained between these two layers. The deep surface of the fascia affords attachment to the superficial fibres of the Temporalis.

The **Temporalis** (fig. 539) is a fan-shaped muscle, situated at the side of the head. It arises from the whole of the temporal fossa (except the part formed by the zygomatic bone) and from the deep surface of the temporal

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Mylohyoideus**, flat and triangular, is situated immediately above the anterior belly of the Digastricus, and forms, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylohyoid line of the mandible. The posterior fibres pass medialwards and slightly downwards, to be inserted into the front of the body of the hyoid bone near its lower border. The middle and anterior fibres are inserted into a median fibrous raphe extending from the mandibular symphysis to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. The median raphe is sometimes wanting; the fibres of the two muscles are then continuous.

Relations.—Its *superficial or inferior surface* is in relation with the Platysma, the anterior belly of the Digastricus, the suprahyoid aponeurosis, the superficial part of the submaxillary gland, the external maxillary and submental vessels, and the mylohyoid vessels and nerve. Its *deep or superior surface* is in relation with the Geniohyoideus, part of the Hyoglossus, and the Styloglossus, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and the submaxillary duct, the lingual and sublingual vessels, and the buccal mucous membrane.

Nerve-supply.—The Mylohyoideus is supplied by the mylohyoid branch of the inferior alveolar nerve.

Actions.—Acting from below the Mylohyoideus depresses the front of the mandible; acting from above it raises the hyoid bone and the floor of the mouth.

The **Geniohyoideus** is a narrow muscle, situated above the medial part of the Mylohyoideus. It arises from the inferior mental spine on the back of the symphysis menti, and runs backwards and slightly downwards, to be inserted into the anterior surface of the body of the hyoid bone; it is in contact with its fellow of the opposite side.

Nerve-supply.—The Geniohyoideus is supplied by the first cervical nerve through the hypoglossal nerve.

Actions.—When the Geniohyoideus acts from the hyoid bone, it depresses the chin of the mandible; when it acts from the mandible it raises and pulls forwards the hyoid bone.

The infrahyoid muscles are:

Sternohyoideus.	Thyreohyoideus.
Sternothyreoideus.	Omohyoideus.

The **Sternohyoideus**, a thin, narrow muscle, arises from the posterior surface of the medial end of the clavicle, the capsule of the sternoclavicular joint, and the upper and posterior part of the manubrium sterni. Passing upwards and medialwards, it is inserted into the lower border of the body of the hyoid bone. It sometimes presents, immediately above its origin, a transverse tendinous inscription. Below, the Sternohyoideus is separated from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and, from this upwards, are contiguous.

Nerve-supply.—The Sternohyoideus is supplied by branches from the loop (ansa hypoglossi) between the descendens hypoglossi and the communicantes cervicales.

Action.—The Sternohyoideus depresses the hyoid bone.

The **Sternothyreoideus** is shorter and wider than the Sternohyoideus, and lies under cover of it. It arises from the posterior surface of the manubrium sterni, below the origin of the Sternohyoideus, and from the edge of the cartilage of the first, and sometimes that of the second, rib; it is inserted into the oblique line on the lamina of the thyreoid cartilage. This muscle is close contact with its fellow at the lower part of the neck, but diverges somewhat as it ascends; it is occasionally traversed by a transverse or oblique tendinous inscription.

Nerve-supply.—The Sternothyreoideus is supplied by branches from the ansa hypoglossi.

Action.—The Sternothyreoideus draws the larynx down.

The **Thyreohyoideus**, a small, quadrilateral muscle, may be looked upon as an upward continuation of the Sternothyreoideus. It arises from the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

oblique line on the lamina of the thyreoid cartilage, and is inserted lower border of the greater cornu of the hyoid bone.

Nerve-supply.—The Thyreohyoideus is supplied by a branch from the hy nerve.

Actions.—The Thyreohyoideus depresses the hyoid bone, or raises the l

The **Omohyoideus** consists of two fleshy bellies united by a central It arises from the upper border of the scapula, and occasionally f superior transverse ligament which crosses the scapular notch, its e attachment to the scapula varying from a few millimetres to 2·5 cm this origin, the *inferior belly* forms a flat, narrow fasciculus, which forwards and slightly upwards across the lower part of the neck, bein to the clavicle by a fibrous expansion; it then passes behind the Ster mastoideus, becomes tendinous and changes its direction, forming an angle. It ends in the *superior belly*, which passes almost vertically close to the lateral border of the Sternohyoideus, and is inserted into th border of the body of the hyoid bone, lateral to the insertion of the hyoideus. The central tendon of this muscle varies in length and for is held in position by a process of the fascia colli, which ensheathes is prolonged down to be attached to the clavicle and first rib; it is means that the angular form of the muscle is maintained.

Nerve-supply.—The superior belly of the Omohyoideus is supplied descendens hypoglossi; the inferior belly by a branch from the ansa hypo

Actions.—The Omohyoideus depresses the hyoid bone and carries it ba and lateralwards. The Omohyoidei are concerned also in prolonged ins efforts; by rendering tense the lower part of the fascia colli they lessen th suction of the soft parts, which would otherwise compress the great vessels apices of the lungs.

The inferior belly of the Omohyoideus divides the posterior triangle of th into an upper or *occipital* and a lower or *subclavian* triangle, while its superi divides the anterior triangle into an upper or *carotid* and a lower or triangle.

III. The Anterior Vertebral Muscles (fig. 544)

Longus colli.	Rectus capitis anterior.
Longus capitis.	Rectus capitis lateralis.

The **Longus colli** is situated on the anterior surface of the vertebral between the atlas and the third thoracic vertebra. It is divisible into portions, a superior oblique, an inferior oblique, and a vertical; its and insertion consist of tendinous slips. The *superior oblique portion* from the anterior tubercles of the transverse processes of the third, and fifth cervical vertebræ; it is directed upwards and medialwards is inserted by a narrow tendon into the tubercle on the anterior arch atlas. The *inferior oblique portion*, the smallest part of the muscle, from the front of the bodies of the first two or three thoracic vertebræ; upwards and lateralwards, and is inserted into the anterior tubercles transverse processes of the fifth and sixth cervical vertebræ. The *portion* arises from the front of the bodies of the upper three thorac lower three cervical vertebræ, and is inserted into the front of the bo the second, third, and fourth cervical vertebræ.

Nerve-supply.—The Longus colli is supplied by branches from the an divisions of the second, third and fourth cervical nerves.

Actions.—The Longus colli bends the cervical portion of the vertebral forwards and lateralwards, and slightly rotates it.

The **Longus capitis** (Rectus capitis anticus major), broad and thick narrow below, arises by tendinous slips, from the anterior tubercles transverse processes of the third, fourth, fifth, and sixth cervical vert and is inserted into the inferior surface of the basilar part of the occ bone.

Nerve-supply.—The Longus capitis is supplied by branches from the an divisions of the first, second and third cervical nerves.

Action.—The Longus capitis flexes the head.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Rectus capitis anterior** (Rectus capitis anticus major) is a short, muscle, situated behind the upper part of the Longus capitis. It arises the anterior surface of the lateral mass of the atlas, and from the root transverse process, and is inserted into the inferior surface of the basilar of the occipital bone in front of the occipital condyle.

Nerve-supply.—The Rectus capitis anterior is supplied by branches from the between the anterior divisions of the first and second cervical nerves.

Action.—The Rectus capitis anterior flexes the head.

FIG. 544.—The anterior and lateral vertebral muscles.

The **Rectus capitis lateralis**, a short, flat muscle, arises from the upper ce of the transverse process of the atlas, and is inserted into the under ce of the jugular process of the occipital bone.

Nerve-supply.—The Rectus capitis lateralis is supplied by branches from the between the anterior divisions of the first and second cervical nerves.

Action.—The Rectus capitis lateralis bends the head lateralwards.

IV. THE LATERAL VERTEBRAL MUSCLES (fig. 544)

Scalenus anterior. Scalenus medius.
Scalenus posterior.

The **Scalenus anterior** lies deeply at the side of the neck, behind the cleidomastoideus. It arises from the anterior tubercles of the transverse sses of the third, fourth, fifth, and sixth cervical vertebræ, and descending, ser vertically, is inserted by a narrow, flat tendon into the scalene tubercle

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

on the inner border of the first rib, and into the ridge on the upper of the rib in front of the subclavian groove.

Relations.—*In front* of it are the clavicle, the Subclavius, Sternocleidomastoid and Omohyoideus muscles, the transverse cervical, transverse scapular and cervical arteries, the subclavian vein, and the phrenic nerve. Its *posterior* relation with the nerves forming the brachial plexus, the subclavian artery, and which separate it from the Scalenus medius. Below, it is separated from colli by the vertebral artery, and above, from the Longus capitis by the cervical branch of the inferior thyreoid artery.

Nerve-supply.—The Scalenus anterior is supplied by branches from the divisions of the fourth, fifth and sixth cervical nerves.

Actions.—Acting from below the Scalenus anterior bends the cervical of the vertebral column forwards and lateralwards and rotates it towards the side. When the muscle acts from above it assists in elevating the thorax.

The **Scalenus medius**, the largest and longest of the three Scaleni from the posterior tubercles of the transverse processes of the lower six vertebræ, and descending along the side of the vertebral column, is by a broad attachment into the upper surface of the first rib, betw tubercle of the rib and the subclavian groove.

Relations.—Its *anterior surface* is in relation with the Sternocleidomastoid crossed by the clavicle and the Omohyoideus; the subclavian artery and the nerves separate it from the Scalenus anterior. *Lateral* to it are the Levator sca the Scalenus posterior. The long thoracic nerve is formed in the substance of the and emerges from it; the dorsal scapular nerve pierces it.

Nerve-supply.—The Scalenus medius is supplied by branches from the divisions of the cervical nerves.

Actions.—The Scalenus medius, acting from below, bends the cervical the vertebral column lateralwards; acting from above it helps to raise the

The **Scalenus posterior**, the smallest and most deeply seated of the Scaleni, arises from the posterior tubercles of the transverse processes lower two or three cervical vertebræ, and is inserted by a thin tend the outer surface of the second rib, behind the attachment of the S anterior. It is occasionally blended with the Scalenus medius.

Nerve-supply.—The Scalenus posterior is supplied by branches from the divisions of the lower three cervical nerves.

Actions.—The Scalenus posterior bends the lower end of the cervical par vertebral column lateralwards, when the second rib is fixed; if its upper atta be fixed it helps to elevate the thorax.

THE FASCIÆ AND MUSCLES OF THE TRUNK

The muscles of the trunk may be arranged in six groups:

I. Deep muscles of the back.
II. Suboccipital muscles.
III. Muscles of the thorax.
IV. Muscles of the abdomen.
V. Muscles of the pelvis.
VI. Muscles of the perinæum.

I. The Deep Muscles of the Back (fig. 546)

The deep or intrinsic muscles of the back consist of a complex group muscles extending from the pelvis to the skull. They are:

Splenius capitis.
Splenius cervicis.
Sacrospinalis.
Semispinalis.
Multifidus.
Rotatores.
Interspinales.
Intertransversarii.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The lumbodorsal fascia covers the deep muscles of the back of the trunk. ve, it passes in front of the Serratus posterior superior and is continuous the *nuchal fascia*, a similar investing layer on the back of the neck.

In the thoracic region the lumbodorsal fascia is a thin fibrous lamina covering tensor muscles of the vertebral column and separating them from the les connecting the vertebral column to the upper extremity. It contains longitudinal and transverse fibres, and is attached, *medially*, to the spinous esses of the thoracic vertebræ; *laterally*, to the angles of the ribs.

In the lumbar region the lumbodorsal fascia (lumbar aponeurosis) is in two rs, anterior and posterior (fig. 545). The posterior layer is attached to the ous processes of the lumbar and sacral vertebræ and to the supraspinal ment; the anterior is attached, *medially*, to the tips of the transverse esses of the lumbar vertebræ, and to the intertransverse ligaments, *below*, the iliolumbar ligament, and *above*, to the lumbocostal ligament (p. 369). e two layers unite at the lateral margin of the Sacrospinalis, to form the on of origin of the Transversus abdominis.

Fig. 545.—A transverse section through the posterior abdominal wall, to show the disposition of the lumbodorsal fascia. Diagrammatic.

The Splenius capitis (fig. 568) arises from the lower half of the ligamentum e, from the spinous process of the seventh cervical vertebra, and from spinous processes of the upper three or four thoracic vertebræ. The fibres the muscle are directed upwards and lateralwards and are inserted, under er of the Sternocleidomastoideus, into the mastoid process of the temporal e, and into the rough surface on the occipital bone just below the lateral d of the superior nuchal line.

Nerve-supply.—The Splenius capitis is supplied by lateral branches of the rior divisions of the middle cervical nerves.

Actions.—The Splenius capitis acts in conjunction with the Splenius cervicis.

The Splenius cervicis (fig. 568) arises from the spinous processes of the d to the sixth thoracic vertebræ; it is inserted into the posterior tubercles the transverse processes of the upper two or three cervical vertebræ.

Nerve-supply.—The Splenius cervicis is supplied by lateral branches of the erior divisions of the lower cervical nerves.

Actions.—The Splenii of the two sides, acting together, draw the head directly kwards; acting separately, they draw the head to one side, and slightly rotate turning the face to the same side.

The Sacrospinalis (Erector spinæ) (fig. 546), and its prolongations in the acic and cervical regions, lie in the groove on the side of the vertebral mn. They are covered in the lumbar and thoracic regions by the lumbo-al fascia, and in the cervical region by the nuchal fascia. They form large muscular and tendinous mass which varies in size and structure at ent parts of the vertebral column. In the sacral region it is narrow pointed, and at its origin chiefly tendinous in structure. In the lumbar n it is larger, and forms a thick fleshy mass which, on being followed ards, is subdivided into three columns; these gradually diminish in size they ascend to be inserted into the vertebræ and ribs.

The Sacrospinalis arises from the anterior surface of a broad and thick ion, which is attached to the middle sacral crest, to the spinous processes

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the lumbar and the eleventh and twelfth thoracic vertebræ, to the spinal ligament, to the posterior part of the inner lip of the iliac crest, to the lateral crest of the sacrum, where it blends with the sacrotuberous and posterior sacro-iliac ligaments; some of its fibres are continuous with fibres of origin of the Glutæus maximus. The muscular fibres form a fleshy mass which splits in the upper lumbar region into three columns, lateral, the *Iliocostalis*, an intermediate, the *Longissimus*, and a medial, *Spinalis*. Each of these consists, from below upwards, of three parts, as follows:

Lateral Column.	*Intermediate Column.*	*Medial Column.*
Iliocostalis.	Longissimus.	Spinalis.
(*a*) I. lumborum.	(*a*) L. dorsi.	(*a*) S. dorsi.
(*b*) I. dorsi.	(*b*) L. cervicis.	(*b*) S. cervicis.
(*c*) I. cervicis.	(*c*) L. capitis.	(*c*) S. capitis.

The **Iliocostalis lumborum** is inserted, by flattened tendons, into the inferior borders of the angles of the lower six or seven ribs.

The **Iliocostalis dorsi** (Musculus accessorius) arises from the upper borders of the angles of the lower six ribs medial to the tendons of insertion of the Iliocostalis lumborum; it is inserted into the upper borders of the angles of the upper six ribs and into the back of the transverse process of the seventh cervical vertebra.

The **Iliocostalis cervicis** (Cervicalis ascendens) arises from the angles of the third, fourth, fifth, and sixth ribs, and is inserted into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

Nerve-supply.—The Iliocostales are supplied by the posterior divisions of the lower cervical, thoracic, and upper lumbar nerves.

Actions.—The Iliocostales are extensors of the vertebral column; they bend it to one side. The slips attached to the ribs act as depressors of the thorax.

The **Longissimus dorsi** is the intermediate and largest of the continuations of the Sacrospinalis. In the lumbar region, where it is as yet blended with the Iliocostalis lumborum, some of its fibres are attached to the whole length of the posterior surfaces of the transverse processes and the accessory processes of the lumbar vertebræ, and to the anterior layer of the lumbar fascia. In the thoracic region it is inserted, by rounded tendons, into the tips of the transverse processes of all the thoracic vertebræ, and by fleshy processes into the lower nine or ten ribs between their tubercles and angles.

The **Longissimus cervicis** (Transversalis cervicis), situated medial to the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the upper four or five thoracic vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ from the second to the sixth inclusive.

The **Longissimus capitis** (Trachelomastoideus) lies between the Longissimus cervicis and the Semispinalis capitis. It arises by tendons from the transverse processes of the upper four or five thoracic vertebræ, and the articular processes of the lower three or four cervical vertebræ, and is inserted into the posterior margin of the mastoid process, beneath the Splenius capitis and Sternocleidomastoideus. It is usually crossed by a tendinous inscription near its insertion.

Nerve-supply.—The Longissimi are supplied by the posterior divisions of the lower cervical, thoracic, and lumbar nerves.

Actions.—The Longissimi dorsi et cervicis bend the vertebral column backwards and lateralwards; the Longissimus capitis extends the head, and turns the face towards the same side.

The **Spinalis dorsi**, the medial continuation of the Sacrospinalis, is scarcely separable as a distinct muscle. It is situated at the medial side of the Longissimus dorsi, and is intimately blended with it; it arises by three or four tendons from the spinous processes of the eleventh and twelfth thoracic, and first and second lumbar, vertebræ: these, uniting, form a small muscle which is inserted by separate tendons into the spinous processes of the upper thoracic vertebræ, the number varying from four to eight. It is intimately united with the Semispinalis dorsi situated beneath it.

The **Spinalis cervicis** is an inconstant muscle, which arises from the part of the ligamentum nuchæ, the spinous process of the seventh cervical sometimes from the spinous processes of the first and second thoracic vertebræ and is inserted into the spinous process of the epistropheus, and occasionally into the spinous processes of the two vertebræ below it.

The **Spinalis capitis** is usually inseparably connected with the spinalis capitis.

Nerve-supply.—The Spinales are supplied by the posterior divisions of the cervical and thoracic nerves.

Actions.—The Spinales extend the vertebral column.

The **Semispinalis dorsi** consists of thin, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of tendons from the transverse processes of the thoracic vertebræ from the sixth to the tenth inclusive, and is inserted, by tendons, into the spinous processes of the upper thoracic and lower two cervical vertebræ.

The **Semispinalis cervicis**, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six thoracic vertebræ, and is inserted into the cervical spinous processes from the epistropheus to the fifth inclusive. The fasciculus connected with the epistropheus is the largest, and is chiefly muscular in structure.

The **Semispinalis capitis** (Complexus) is situated at the back part of the neck, beneath the Splenius, and medial to the Longissimi cervicis et capitis. It arises by a series of tendons from the tips of the transverse processes of the upper six or seven thoracic and the seventh cervical vertebræ, and from the articular processes of the fourth, fifth, and sixth cervical vertebræ. These tendons are succeeded by a broad muscle which passes upwards and is inserted between the superior and inferior nuchal lines of the occipital bone. The medial part, usually more or less distinct from the remainder of the muscle, is termed the *Spinalis capitis*; it is also named the *Biventer cervicis* since it is traversed by an imperfect tendinous inscription.

Nerve-supply.—The Semispinales are supplied by the posterior divisions of the cervical and thoracic nerves.

Actions.—The Semispinalis dorsi et cervicis extend the thoracic and cervical portions of the vertebral column, and rotate them towards the opposite side. Semispinalis capitis extends the head, and turns the face slightly towards the opposite side.

The **Multifidus** consists of a number of fleshy and tendinous fasciculi which fill the groove on the side of the spinous processes of the vertebræ, from the sacrum to the epistropheus. In the sacral region, the fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, from the aponeurosis of origin of the Sacrospinalis, from the medial surface of the posterior superior iliac spine, and from the posterior sacro-iliac ligaments; in the lumbar region from all the mamillary processes; in the thoracic region, from all the transverse processes; and in the cervical region, from the articular processes of the lower four vertebræ. Each fasciculus passes obliquely upwards and medialwards and is inserted into the whole length of the spinous process of one of the vertebræ above. The fasciculi vary in length: the most superficial reach from one vertebra to the third or fourth above; those next in order run from one vertebra to the second or third above; while the deepest connect contiguous vertebræ.

Nerve-supply.—The Multifidus is supplied by the posterior divisions of the spinal nerves.

Actions.—The fasciculi of the Multifidus bend the segments of the vertebral column backwards and lateralwards, and rotate them towards the opposite side.

The **Rotatores** lie beneath the Multifidus and are found only in the thoracic region; they are eleven in number on either side, and are small and somewhat quadrilateral in form. Each arises from the upper and posterior part of the transverse process, and is inserted into the lower border and lateral surface of the lamina of the vertebra above, the fibres extending as far as the root of the spinous process. The first is found between the first and second thoracic vertebræ; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end of the series.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Nerve-supply.—The Rotatores are supplied by the posterior divisions of the spinal nerves.

Actions.—The Rotatores mainly rotate the individual vertebræ towards the opposite side.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on either side of the interspinal ligament. In the *cervical region* they are most distinct, and consist of six pairs, the first being situated between the epistropheus and third vertebra, and the last between the seventh cervical and the first thoracic. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *thoracic region* they are found between the first and second vertebræ, and sometimes between the second and third, and the eleventh and twelfth. In the *lumbar region* there are four pairs in the intervals between the five lumbar vertebræ. A pair is occasionally found between the last thoracic and first lumbar, and another between the fifth lumbar and the sacrum.

Nerve-supply.—The Interspinales are supplied by the posterior divisions of the spinal nerves.

Actions.—The Interspinales extend those segments of the vertebral column to which they are attached.

The **Extensor coccygis** is a slender muscular fasciculus, which is not always present; it extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last segment of the sacrum, or first piece of the coccyx, and passes downwards to be inserted into the lower part of the coccyx. It is a rudiment of the Levator caudæ muscle of the lower animals.

The **Intertransversarii** are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are best developed and consist of paired fasciculi which pass between the anterior and the posterior tubercles respectively of the transverse processes of two contiguous vertebræ; the muscles of each pair are separated by the anterior division of the cervical nerve, which lies in the groove between them. The muscles connecting the anterior tubercles are termed the *Intertransversarii anteriores*; those between the posterior tubercles the *Intertransversarii posteriores*. There are seven pairs of these muscles, the first pair being between the atlas and epistropheus, and the last between the seventh cervical and first thoracic vertebræ. In the *thoracic region* they are present between the transverse processes of the lower three thoracic, and between the transverse processes of the last thoracic and the first lumbar vertebræ. In the *lumbar region* they are arranged in pairs, on either side of the vertebral column; one set, occupying the entire interspace between the transverse processes of the lumbar vertebræ, the *Intertransversarii laterales*; the other set, *Intertransversarii mediales*, passing from the accessory process of one vertebra to the mamillary of the vertebra below.

Nerve-supply.—The Intertransversarii mediales are supplied by posterior divisions of the spinal nerves; all the others are supplied by anterior divisions.

Actions.—The Intertransversarii act as lateral flexors of those segments of the vertebral column to which they are attached.

II. The Suboccipital Muscles (fig. 546)

Rectus capitis posterior major.	Obliquus capitis inferior.
Rectus capitis posterior minor.	Obliquus capitis superior.

The **Rectus capitis posterior major** arises by a pointed tendon from the spinous process of the epistropheus and, becoming broader as it ascends, is inserted into the lateral part of the inferior nuchal line of the occipital bone, and also into the bone immediately below the line. As the muscles of the two sides pass upwards and lateralwards, they leave between them a triangular space, in which the Recti capitis posteriores minores are seen.

Nerve-supply.—The Rectus capitis posterior major is supplied by the posterior division of the suboccipital nerve.

Actions.—The Rectus capitis posterior major extends the head, and turns the face towards the same side.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Rectus capitis posterior minor** arises by a narrow pointed from the tubercle on the posterior arch of the atlas, and, widening ascends, is inserted into the medial part of the inferior nuchal line occipital bone and also into the bone between that line and the magnum.

Nerve-supply.—The Rectus capitis posterior minor is supplied by the division of the suboccipital nerve.

Action.—The Rectus capitis posterior minor extends the head.

The **Obliquus capitis inferior**, the larger of the two Oblique arises from the apex of the spinous process of the epistropheus, and lateralwards and slightly upwards, to be inserted into the lower and of the transverse process of the atlas.

Nerve-supply.—The Obliquus capitis inferior is supplied by the posterior of the suboccipital nerve.

Action.—The Obliquus capitis inferior turns the face towards the same

The **Obliquus capitis superior**, narrow below, wide and expanded arises by tendinous fibres from the upper surface of the transverse the atlas, joining with the insertion of the Obliquus capitis inferior. upwards and medialwards, and is inserted into the occipital bone, superior and inferior nuchal lines, lateral to the Semispinalis capitis.

Nerve-supply.—The Obliquus capitis superior is supplied by the posterior of the suboccipital nerve.

Actions.—The Obliquus capitis superior bends the head backwards and wards.

The suboccipital triangle.—This triangle is bounded, above and medial the Rectus capitis posterior major; above and laterally, by the Obliquus superior; below and laterally, by the Obliquus capitis inferior. It is covered a layer of dense fibrofatty tissue, situated beneath the Semispinalis capitis. floor is formed by the posterior occipito-atlantal membrane, and the posterior of the atlas. In the groove on the upper surface of the posterior arch of the are the vertebral artery and the first cervical nerve.

III. The Muscles of the Thorax

Intercostales externi.	Levatores costarum.
Intercostales interni.	Serratus posterior superior.
Subcostales.	Serratus posterior inferior.
Transversus thoracis.	Diaphragm.

The **Intercostales** (fig. 570) are two thin plates of muscular and tendinous fibres occupying each of the intercostal spaces. They are named *external* and *internal* from their surface relations—the external being superficial the internal.

The **Intercostales externi** are eleven in number on either side. attachments extend from the tubercles of the ribs behind, to near the cartilages of the ribs in front, where each is replaced by a layer of fascia named the *intercostal membrane*, which is continued forwards to the sternum. Each arises from the lower border of one rib, and is inserted into the upper of the rib below. In the lower two spaces they extend to the ends of the cartilages, and in the upper two or three spaces they do not quite reach the of the ribs. They are thicker than the Intercostales interni, and their are directed obliquely downwards and lateralwards on the back of the and downwards, forwards, and medialwards on the front.

The **Intercostales interni** are also eleven in number on either side. attachments commence anteriorly at the sternum, in the interspaces the cartilages of the true ribs, and at the anterior extremities of the of the false ribs, and extend backwards as far as the angles of the ribs, each is replaced by a layer of fascia named the *posterior intercostal* which is continuous with the anterior costotransverse ligament. Each arises from the ridge on the inner surface of one rib, as well as from corresponding costal cartilage, and is inserted into the upper border of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Their fibres are also directed obliquely, but at right angles to those of
Intercostales externi.*

Nerve-supply.—The Intercostales externi et interni are supplied by the inter-
nerves.

Actions.—The Intercostales externi et interni have probably little action in
the ribs. They contract simultaneously and form strong elastic supports
prevent the intercostal spaces being drawn in or bulged out during respir-
The anterior portions of the Intercostales interni probably have an
additional function in keeping the sternocostal and interchondral joint-surfaces in
position, the posterior portions of the Intercostales externi performing a similar
function for the costovertebral joints.

The **Subcostales** consist of muscular and aponeurotic fasciculi, and are
only well developed in the lower part of the thorax; each arises from
inner surface of one rib near its angle, and is inserted into the inner
surface of the second or third rib
below. Their fibres run in the same
direction as those of the Intercos-
tales interni.

Nerve-supply.—The Subcostales
are supplied by intercostal nerves.

Actions.—The Subcostales depress
the ribs.

The **Transversus thoracis**
(Triangularis sterni) is a thin plane
of muscular and tendinous fibres,
situated upon the inner surface of
the front wall of the chest (fig. 547).
It arises on either side from the
lower third of the posterior surface
of the body of the sternum, from
the posterior surface of the xiphoid
process, and from the posterior
surfaces of the costal cartilages of
the lower three or four true ribs
near their sternal ends. Its fibres
converge upwards and lateralwards,
to be inserted by slips into the
lower borders and inner surfaces of
the costal cartilages of the second,
third, fourth, fifth, and sixth ribs.
The lowest fibres of this muscle are
horizontal, and are continuous with
those of the Transversus abdominis;
the intermediate fibres are oblique,
while the highest are almost vertical.
This muscle varies in its attach-
ments not only in different subjects,
but on opposite sides of the same
subject.

Fig. 547.—The left Transversus thoracis. Posterior aspect.

Nerve-supply.—The Transversus thoracis is supplied by intercostal nerves.

Actions.—The Transversus thoracis draws down the costal cartilages to which it is attached.

The **Levatores costarum** (fig. 546), twelve in number on either side, are
long bundles, which arise from the ends of the transverse processes of the
seventh cervical and upper eleven thoracic vertebræ; they pass obliquely down-
wards and lateralwards, parallel with the posterior borders of the Intercostales
externi, and each is inserted into the upper edge and outer surface of the rib
immediately below the vertebra from which it takes origin, between the

* T. Walmsley (*Journal of Anatomy*, vol. l.) describes each Internal intercostal muscle as consisting of (*a*) a superficial part, confined to the anterior two-thirds of the intercostal space, and properly named the Intercostalis internus, and (*b*) a deep or *intracostal* part, present in the middle two-fourths of each space, and in the same plane as the Transversus thoracis and the Subcostalis.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tubercle and the angle (Levatores costarum breves). Each of the four muscles divides into two fasciculi, one of which is inserted as above described, the other passes down to the second rib below its origin (Levatores costarum longi).

Nerve-supply.—The Levatores costarum are supplied by the intercostal nerves.

Actions.—The Levatores costarum being inserted near the fulcra of the ribs, have little or no elevating action on the ribs; they act as rotators and lateral flexors of the vertebral column.

The **Serratus posterior superior** is a thin, quadrilateral muscle, situated at the upper and posterior part of the thorax. It arises by a thin aponeurosis from the lower part of the ligamentum nuchæ, from the spinous processes of the seventh cervical and upper two or three thoracic vertebræ and

Fig. 548.—The posterior one-half of the Diaphragm. Anterior aspect. (Modified from a model by His.)

the supraspinal ligament. Inclining downwards and lateralwards it is inserted by four fleshy digitations, into the upper borders and outer surfaces of the second, third, fourth, and fifth ribs, a little beyond their angles.

Nerve-supply.—The Serratus posterior superior is supplied by the second, third, fourth and fifth intercostal nerves.

Actions.—The Serratus posterior superior elevates the ribs.

The **Serratus posterior inferior** (fig. 568) is situated at the junction of the thoracic and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a wide interval. It arises by a thin aponeurosis from the spinous processes of the lower two thoracic and upper two or three lumbar vertebræ, and from the supraspinal ligament; this aponeurosis is intimately blended with the lumbodorsal fascia. Passing obliquely upwards and lateralwards, it becomes fleshy, and is inserted by four digitations into the inferior borders and outer surfaces of the lower four ribs, a little beyond their angles.

Nerve-supply.—The Serratus posterior inferior is supplied by the ninth, tenth, eleventh and twelfth thoracic nerves.

Actions.—The Serratus posterior inferior draws the lower ribs downwards and backwards and thus elongates the thorax; it also fixes the lower ribs, thus assisting the inspiratory action of the Diaphragm and resisting the tendency of the latter to draw the lower ribs upwards and forwards.

The **Diaphragm** (figs. 548, 549) is a dome-shaped musculofibrous septum which separates the thoracic from the abdominal cavity, its convex

Digitized by Arya Samaj Foundation Chennai and eGangotri

The medial tendinous margins of the crura occasionally meet in the line to form an arch across the front of the aorta; this arch is often defined.

From this series of origins the fibres of the Diaphragm converge to inserted into the central tendon. The fibres arising from the xiphoid are very short, and occasionally aponeurotic; those from the ribs and lateral lumbocostal arches, and more especially those from the ribs and cartilages, are longer, and describe marked curves as they ascend and to their insertion. The fibres arising from the crura diverge as they the most lateral being directed upwards and lateralwards to the centre. The medial fibres of the right crus ascend on the left side of the œsophageal hiatus, and occasionally a fasciculus of the left crus crosses the aorta, runs obliquely through the fibres of the right crus towards the venacaval foramen (Low *).

The *central tendon* of the Diaphragm is a thin but strong aponeurosis near the centre of the vault formed by the muscle, but somewhat nearer the front than to the back of the thorax, so that the posterior muscular fibres are the longer. It is situated immediately below the pericardium, with which it is partially blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions or leaflets separated from one another by slight indentations. The right leaflet is the largest, the middle, directed towards the xiphoid process, the next in size, and the left the smallest. In structure the tendon is composed of several planes of fibres, which intersect one another at right angles and unite into straight or curved bundles—an arrangement which gives it additional strength.

Openings in the Diaphragm.—The Diaphragm is pierced by a number of apertures to permit of the passage of structures between the thorax and abdomen. Three large openings—the aortic, the œsophageal, and the venacaval—and a number of smaller ones are present.

The *aortic hiatus* is the lowest and most posterior of the large apertures; it lies at the level of the twelfth thoracic vertebra slightly to the left of the middle line. Strictly speaking, it is an osseo-aponeurotic opening between the vertebral column and the Diaphragm, and therefore behind the latter. Occasionally some tendinous fibres from the medial parts of the crura pass behind the aorta, and convert the hiatus into a fibrous ring. Through it pass the aorta, the azygos vein, and the thoracic duct; occasionally the azygos vein pierces the right crus.

The *œsophageal hiatus* is situated in the muscular part of the Diaphragm at the level of the tenth thoracic vertebra; it is elliptical in shape, and "formed by the splitting of the medial fibres of the right-crus" (Low). It is placed above, in front, and a little to the left of the aortic hiatus, and transmits the œsophagus, the vagus nerves, and some small œsophageal vessels.

The *venacaval foramen* is the highest of the three, and is situated at the level of the fibrocartilage between the eighth and ninth thoracic vertebrae. It is quadrilateral in form, and is placed at the junction of the right and middle leaflets of the central tendon, so that its margins are tendinous. It transmits the inferior vena cava, the wall of which is adherent to the margins of the opening, and some branches of the right phrenic nerve.

Of the *lesser apertures*, two in the right crus transmit the greater and lesser right splanchnic nerves; three in the left crus give passage to the greater and lesser left splanchnic nerves and the hemiazygos vein. The gangliated trunks of the sympathetic usually enter the abdominal cavity behind the Diaphragm under the medial lumbocostal arches. The structures piercing the crura are sometimes utilised to divide each crus into medial, intermediate, and lateral parts, the last consisting of the fibres arising from the medial lumbocostal arch. Between the medial and intermediate parts the hemiazygos vein and the splanchnic nerves pass; between the intermediate and lateral parts the gangliated trunks of the sympathetic occasionally pass.

On either side two small intervals exist at which the muscular fibres of the Diaphragm are deficient and are replaced by areolar tissue. One between the sternal and costal parts transmits the superior epigastric branch of the internal mammary artery, and some lymphatics from the abdominal wall.

* Alex. Low, *Journal of Anatomy and Physiology*, vol. xlii.

Digitized by Arya Samaj Foundation Chennai and eGangotri

ax surface of the liver. The other, between the fibres springing from medial and lateral lumbocostal arches, is less constant; when this interval the upper and back part of the kidney is separated from the pleura by tissue only.

ations.—The upper surface of the Diaphragm is in relation with three serous ranes, viz. on either side the pleura, which separates it from the base of the ponding lung, and on the middle leaflet of the central tendon the pericardium, intervenes between it and the heart. The central portion lies on a slightly lower than the summits of the lateral portions. The greater part of the under surface ered by the peritoneum. The right side is accurately moulded over the convex of the right lobe of the liver, the right kidney, and right suprarenal gland; the r the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney, left suprarenal gland.

erve-supply.—The Diaphragm is supplied by the phrenic nerve and the lower seven intercostal nerves.

ctions.—The Diaphragm is the principal muscle of inspiration, and presents orm of a dome concave towards the abdomen. The central part of the dome ninous, and the pericardium is attached to its upper surface; the circum- is muscular. During inspiration the lowest ribs are fixed, and from these e crura the muscular fibres contract and draw downwards and forwards the tendon with the attached pericardium. In this movement the curvature Diaphragm is scarcely altered, the dome moving downwards nearly parallel original position and pushing before it the abdominal viscera. The descent abdominal viscera is permitted by the extensibility of the abdominal wall, but mit of this is soon reached. The central tendon applied to the abdominal n then becomes a fixed point for the action of the Diaphragm, the effect of is to elevate the lower ribs and through them to push forwards the body sternum and the upper ribs. The right cupola of the Diaphragm, lying on iver, has a greater resistance to overcome than the left, which lies over the ch, but to compensate for this the right crus and the fibres of the right side ly are stronger than those of the left.

all expulsive acts the Diaphragm is called into action to give additional power effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and ns to the expulsion of urine or fæces, or of the fœtus from the uterus, a deep ation takes place.

The height of the Diaphragm is constantly varying during respiration; it also s with the degree of distension of the stomach and intestines and with the of the liver. After a forced expiration the right cupola is on a level in front the fourth costal cartilage, at the side with the fifth, sixth, and seventh ribs, hind with the eighth rib; the left cupola is a little lower than the right. Dally* states that the absolute range of movement between deep inspiration eep expiration averages in the male and female 30 mm. on the right side and on the left; in quiet respiration the average movement is 12·5 mm. on the side and 12 mm. on the left.

ography shows that the height of the Diaphragm in the thorax varies considerably the position of the body. It stands highest when the body is horizontal and the on his back, and in this position it performs the largest respiratory excursions normal breathing. When the body is erect the dome of the Diaphragm falls, and piratory movements become smaller. The dome falls still lower when the sitting e is assumed, and in this position its respiratory excursions are smallest. When the is horizontal and the patient on his side, the two halves of the Diaphragm do not e alike. The uppermost half sinks to a level lower even than when the patient sits, ves little with respiration; the lower half rises higher in the thorax than it does the patient is supine, and its respiratory excursions are much increased.

ears that the position of the Diaphragm in the thorax depends upon three main s, viz.: (1) the elastic retraction of the lung-tissue, tending to pull it upwards; pressure exerted on its under surface by the viscera: this naturally tends to be a ve pressure, or downward suction, when the patient sits or stands, and a positive, ard pressure, when he lies; (3) the intra-abdominal tension due to the abdominal es. These muscles are in a state of contraction in the standing position and not in ting; hence the Diaphragm is pushed up higher in the former position.

* *Journal of Anatomy and Physiology*, vol. xliii.

Applied Anatomy.—The oblique rise of the Diaphragm from the costal [illegible] level of the fifth costal cartilage on the right side, and the sixth on the left, ha[illegible] in mind in opening an empyema. If the drainage tube be put in too low do[illegible] abscess cavity contracts the Diaphragm is drawn up against and blocks the [illegible] the abscess is cured.

The Mechanism of Respiration

The respiratory movements must be examined during (*a*) quiet respi[illegible] (*b*) deep respiration.

Quiet respiration.—The first and second pairs of ribs are fixed by the [illegible] of the cervical structures; the last pair, and through them the eleventh [illegible] Quadratus lumborum. The other ribs are elevated, so that the first two [illegible] spaces are diminished while the others are increased in width. It has al[illegible] shown (p. 373) that elevation of the third, fourth, fifth, and sixth ribs le[illegible] increase in the anteroposterior and transverse diameters of the thorax: th[illegible] diameter is increased by the descent of the diaphragmatic dome so that [illegible] are expanded in all directions except backwards and upwards. Elevati[illegible] eighth, ninth, and tenth ribs is accompanied by a lateral and backward m[illegible] leading to an increase in the transverse diameter of the upper part of the a[illegible] the elasticity of the anterior abdominal wall allows a slight increase in th[illegible] posterior diameter of this part, and in this way the decrease in the vertical [illegible] of the abdomen is compensated and space provided for its displaced viscera. [illegible] tion is effected by the elastic recoil of its walls and by the action of the a[illegible] muscles, which push back the viscera displaced downwards by the Diaph[illegible]

Deep respiration.—All the movements of quiet respiration are here ex[illegible] but to a greater extent. In deep respiration the shoulders and the vertebr[illegible] of the scapulæ are fixed and the limb muscles, the Trapezius, Serratus [illegible] Pectorales, and Latissimus dorsi, called into play. The Scaleni are i[illegible] action, and the Sternocleidomastoidei also assist, when the head is fixed, by [illegible] up the sternum and by fixing the clavicles. The first rib is therefore [illegible] stationary, but, with the sternum, is raised; with it all the other ribs ex[illegible] last are raised to a higher level. In conjunction with the increased descen[illegible] Diaphragm this provides for a considerable augmentation of all the [illegible] diameters. The anterior abdominal muscles come into action so that the [illegible] is drawn upwards and backwards, but this allows the Diaphragm to exert [illegible] powerful influence on the lower ribs; the transverse diameter of the upper [illegible] the abdomen is greatly increased and the subcostal angle opened out. Th[illegible] muscles of the back, e.g. the Serrati posteriores superiores and the Sacro[illegible] and their continuations, are also brought into action; the thoracic curv[illegible] vertebral column is partially straightened, and the whole column, above th[illegible] lumbar vertebræ, drawn backwards. This increases the anteroposterior di[illegible] of the thorax and upper part of the abdomen and widens the intercostal [illegible] Deep expiration is effected by the recoil of the walls and by the contractio[illegible] anterolateral muscles of the abdominal wall, and the Transversus thoracis.

Halls Dally (*loc. cit.*) gives the following figures as representing the average [illegible] which occur during deepest possible respiration. The manubrium sterni moves [illegible] in an upward and 14 mm. in a forward direction; the width of the subcostal an[illegible] level of 30 mm. below the articulation between the body of the sternum and the [illegible] process, is increased by 26 mm.; the umbilicus is retracted and drawn upwa[illegible] distance of 18 mm.

Applied Anatomy.—The changes in the height of the Diaphragm during alter[illegible] posture explain why patients suffering from severe dyspnœa are most comfort[illegible] least short of breath when they sit up. In unilateral disease of the pleura or lu[illegible] ference with the position or movement of the Diaphragm can generally be obser[illegible] graphically.

The referred pains felt when the Diaphragm is inflamed are described with the [illegible] of the phrenic nerve.

The Obliquus externus abdominis (fig. 550), situated on the lateral and anterior parts of the abdomen, is the largest and the most superficial of the broad flat muscles in this region. It arises, by eight fleshy slips, from the external surfaces and inferior borders of the lower eight ribs; these slips digitate with the slips of origin of the Serratus anterior and Latissimus and are arranged in an oblique line which runs downwards and backwards, the upper ones being attached close to the cartilages of the corresponding ribs, the lowest to the apex of the cartilage of the last rib, the intermediate ones to

Fig. 552.—A superficial dissection of the groin and the lower part of the anterior abdominal wall. Left side.

ribs at some distance from their cartilages. From these attachments the fibres proceed in various directions. Those from the lowest ribs pass vertically downwards, and are inserted into the anterior half of the lip of the iliac crest; the middle and upper fibres, directed downwards wards, end in an aponeurosis, opposite a line drawn from the prominence ninth costal cartilage to the anterior superior iliac spine. The posterior of the muscle is free.

The *aponeurosis* of the Obliquus externus abdominis is a thin but strong membranous structure, the fibres of which are directed downwards and medialwards. It is joined with that of the opposite muscle along the middle line, and aponeuroses of the two muscles cover the front of the abdomen; above, covered by, and gives origin to, the lower fibres of the Pectoralis major; its fibres are closely aggregated together, and extend obliquely across the anterior superior iliac spine to the pubic tubercle and the pectineal In the middle line, its fibres end in the *linea alba* (fig. 550), a tendinous which extends from the xiphoid process to the symphysis pubis.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The margin of that portion of the aponeurosis which extends be anterior superior iliac spine and the pubic tubercle is a thick ba inwards upon itself to present a grooved upper surface, and contin with the fascia lata; it is called the *inguinal ligament*. A small reflected from the medial part of the inguinal ligament, and is attac pecten pubis; it is called the *lacunar ligament*. From the attachm latter to the pecten pubis, a few fibres pass upwards and medialwar the medial crus of the subcutaneous inguinal ring, to the linea alb diverge as they ascend, and form a thin triangular fibrous band whic the *reflected inguinal ligament* (fig. 557).

In the aponeurosis of the Obliquus externus, immediately above of the os pubis, is a triangular opening, the *subcutaneous inguinal ring* by a separation of the fibres of the aponeurosis in this situation.

Nerve-supply.—The Obliquus externus abdominis is supplied by the divisions of the lower thoracic nerves.

Actions.—When the thorax and pelvis are fixed the Obliqui externi a compress the abdominal viscera and thus assist in expelling the fæces from the urine from the bladder, the fœtus from the uterus, and the conte stomach in vomiting. If the pelvis and vertebral column be fixed the depress and compress the lower part of the thorax, assisting in expir the pelvis alone be fixed, the trunk is bent forwards when both muscles a muscle of one side act, the trunk is bent towards that side and the front of men turned towards the opposite side. If the thorax be fixed the muscl together, draw the front of the pelvis upwards; acting singly they will i bend the lumbar part of the vertebral column, and turn the front of the to the same side.

The following structures require further description, viz. the sub inguinal ring, the intercrural fibres and fascia, and the inguinal, lacu reflected inguinal ligaments.

The **subcutaneous inguinal ring** (external abdominal ring) (figs. is an interval in the aponeurosis of the Obliquus externus, just above a to the crest of the os pubis. The aperture is somewhat triangular in f its direction is oblique, corresponding with the course of the fibres aponeurosis. It measures from base to apex about 2·5 cm., and a base about 1·25 cm. It is bounded below by the crest of the os pubis; o side by the margins of the opening in the aponeurosis, which are ca *crura of the ring*; and above, by a series of curved *intercrural fibr* inferior crus (external pillar) is the stronger, and is formed by that portio inguinal ligament which is inserted into the pubic tubercle; it is so c to form a kind of groove, upon which, in the male, the spermatic cor The superior crus (internal pillar) is a thin, flat band, attached to th of the symphysis pubis and interlacing with its fellow of the opposite sid

The subcutaneous inguinal ring gives passage to the spermatic c ilio-inguinal nerve in the male, and to the round ligament of the ute the ilio-inguinal nerve in the female; it is much larger in men than i on account of the size of the spermatic cord.

The **intercrural fibres** (intercolumnar fibres) are a series of tendinous fibres, which arch across the lower part of the aponeuros Obliquus externus, describing curves with the convexities downwards have received their name from stretching across between the two c the subcutaneous inguinal ring, and they are much thicker and strong inferior crus, where they are connected to the inguinal ligament, than su where they are inserted into the linea alba. The intercrural fibres the strength of the lower part of the aponeurosis, and tend to prev divergence of the crura from one another; they are more strongly d in the male than in the female.

As they pass across the subcutaneous inguinal ring, they are c together by delicate fibrous tissue, forming a fascia, called the *fascia*. This **intercrural fascia** is continued down as a tubular p tion around the spermatic cord and testis, and encloses them in a hence it is also called the *external spermatic fascia*. The subcutaneous ring is seen as a distinct aperture only after the intercrural fascia h removed.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **inguinal ligament** (Poupart's ligament) (figs. 551 to 553) is the lower
er of the aponeurosis of the Obliquus externus, and extends from the
rior superior iliac spine to the pubic tubercle. Its general direction is
r downwards towards the thigh, where it is continuous with the fascia
Its lateral one-half is rounded, and oblique in direction; its medial
lf gradually widens at its attachment to the os pubis, is more horizontal
rection, and supports the spermatic cord.

The **lacunar ligament** (Gimbernat's ligament) (fig. 553) is that portion of the
eurosis of the Obliquus externus which is reflected backwards and lateral-
s from the medial part of the inguinal ligament, and is attached to the
os pubis. It is of a triangular form, and is almost horizontal in direction

FIG. 553.—The left inguinal and lacunar ligaments.

n the body is in the erect posture; it is a little larger in the male than
he female, and measures about 2 cm. from base to apex. Its base,
ed laterally, is concave and thin and forms the medial boundary of the
ral ring; its apex corresponds to the pubic tubercle. Its posterior margin
ached to the pecten pubis, and is continuous with the pectineal fascia;
nterior margin blends with the inguinal ligament. Its surfaces are directed
rds and downwards.

The **reflected inguinal ligament** (triangular fascia) (figs. 552, 557) is a
gular-shaped layer of tendinous fibres; it is formed by an expansion
the lacunar ligament and the inferior crus of the subcutaneous inguinal
It passes medialwards behind the spermatic cord, expands into a some-
fan-shaped band behind the superior crus of the subcutaneous inguinal
and in front of the inguinal aponeurotic falx, and interlaces with the
ent of the other side at the linea alba.

gament of Cooper.—This is a strong fibrous band, which was first described
Astley Cooper. It extends lateralwards from the base of the lacunar
ent (fig. 553) along the pecten pubis, to which it is attached. It is
gthened by the pectineal fascia, and by a lateral expansion from the lower
ment of the linea alba (adminiculum lineæ albæ).

The **Obliquus internus abdominis** (fig. 554), thinner and smaller than the Obliquus externus, beneath which it lies, is of an irregularly quadrilateral form. It arises, by fleshy fibres, from the lateral one-half of the groove on the surface of the inguinal ligament, from the anterior two-thirds of the middle lip of the iliac crest, and from the posterior lamella of the lumbodorsal fascia. From this origin the fibres diverge; those from the inguinal ligament are few in number, and paler in colour than the rest, arch downwards and medialwards across the spermatic cord in the male, and the round ligament of the uterus in the female, and, becoming tendinous, are inserted, conjointly with

FIG. 554.—The left Obliquus internus abdominis.

the Transversus, into the crest of the os pubis and into the medial part of the pecten pubis behind the lacunar ligament, forming what is known as the inguinal aponeurotic falx. Those from the anterior one-third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower one-third of the linea semilunaris, pass in front of the Rectus abdominis to be inserted into the linea alba. Those arising from the middle one-third of the iliac crest run obliquely upwards and medialwards, and end in an aponeurosis which divides at the lateral border of the Rectus into two lamellæ, which are carried forwards, one in front of and the other behind this muscle, to the linea alba; the posterior lamella has an attachment to the cartilages of the seventh, eighth and ninth ribs. The most posterior fibres pass almost vertically upwards to be inserted into the inferior borders of the cartilages of the lower three, being continuous with the Intercostales interni.

Nerve-supply.—The Obliquus internus abdominis is supplied by the anterior divisions of the lower thoracic and first lumbar nerves.

Digitized by Arya Samaj Foundation Chennai and eGangotri

ions.—The actions of the Obliqui interni abdominis are similar to those of liqui externi in compressing the abdomen (p. 472). Acting from below the s internus bends the thorax and turns the front of the abdomen towards e side; acting from above it bends the lumbar part of the vertebral column wn side and turns the front of the abdomen to the opposite side.

Cremaster (figs. 554, 556) is a thin muscular layer, composed of a of fasciculi which arise from the middle of the inguinal ligament, where

FIG. 555.—The left Transversus abdominis and right Rectus abdominis.

es are continuous with those of the Obliquus internus and also occasionally the Transversus. It passes along the lateral side of the spermatic cord, ds with it through the subcutaneous inguinal ring upon the front and of the cord, and forms a series of loops which differ in thickness and in different subjects. At the upper part of the cord the loops are short, ey become successively longer, the longest reaching down as far as the where a few are inserted into the tunica vaginalis. These loops are d together by areolar tissue, and form a thin covering over the cord and the *cremasteric fascia*. The fibres ascend along the medial side of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

cord, and are inserted by a small pointed tendon into the tubercle of the os pubis and into the front of the sheath of the Rectus abdominis.

Nerve-supply.—The Cremaster is supplied by the external spermatic of the genitofemoral nerve.

Action.—The Cremaster is an involuntary muscle which pulls up the testis.

The **Transversus abdominis** (fig. 555), so called from the direction of its fibres, is the most internal of the flat muscles of the abdomen, being deep to the Obliquus internus. It arises by fleshy fibres from the

FIG. 556.—A dissection of the regions shown in fig. 551, but with a part of the Obliquus externus removed.

one-third of the inguinal ligament, from the anterior three-fourths of the lip of the iliac crest, from the inner surfaces of the cartilages of the lower ribs, interdigitating with the Diaphragm, and from the lumbodorsal fascia. The muscle ends in front in a broad aponeurosis, the lower fibres of which curve downwards and medialwards, and are inserted, together with those of the Obliquus internus, into the crest of the os pubis and pecten pubis, forming the inguinal aponeurotic falx. Throughout the rest of its extent the aponeurosis passes horizontally to the middle line, and is inserted into the linea alba; its upper three-fourths lie behind the Rectus and blend with the posterior lamella of the aponeurosis of the Obliquus internus; its lower one-fourth in front of the Rectus.

The *inguinal aponeurotic falx*, or *conjoined tendon* of the Obliquus internus and Transversus (figs. 557, 558), is mainly formed by the lower part of the tendon of the Transversus, and is inserted into the crest of the os pubis and pecten pubis, immediately behind the subcutaneous inguinal ring, serving to protect what would otherwise be a weak point in the abdominal wall. It

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the falx is a ligamentous band connected with the lower margin of the transversus and extending down to the superior ramus of the os pubis; it is named the *interfoveolar ligament* (of Hesselbach) (fig. 558), and sometimes contains a few muscular fibres.

Nerve-supply.—The Transversus abdominis is supplied by the anterior divisions of the lower thoracic and first lumbar nerves.

Actions.—The Transversi abdominis almost completely encircle the abdominal cavity; in action they compress the abdominal contents.

FIG. 557.—A dissection of the regions shown in fig. 552, but with portions of the Obliqui externus et internus removed.

Rectus abdominis (fig. 559) is a long flat muscle, broader above than below, which extends along the whole length of the front of the abdomen, and is separated from its fellow of the opposite side by the linea alba. It arises by two tendons; the lateral and larger is attached to the crest of the pubis, the medial interlaces with its fellow of the opposite side and is continuous with the ligamentous fibres covering the front of the symphysis pubis. The muscle is inserted by three slips of unequal size into the cartilages of the fifth, sixth, and seventh ribs; some fibres of the upper slip are usually inserted into the anterior extremity of the fifth rib; some are occasionally connected with the costoxiphoid ligaments and the side of the xiphoid process.

The Rectus is crossed by three fibrous bands, named *tendinous inscriptions*; one is usually situated opposite the umbilicus, the second opposite the end of the xiphoid process, and the third about midway between the xiphoid process and the umbilicus. These inscriptions pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance and may pass only halfway across it; they are intimately

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

adherent to the anterior lamina of the sheath of the muscle. Sometimes two additional but incomplete inscriptions are present below the umbilicus.

The Rectus abdominus is enclosed in a sheath (figs. 554, 559, 560) formed by the aponeuroses of the Obliqui and Transversus, which are arranged as follows. At the lateral margin of the Rectus, the aponeurosis of the Obliquus externus divides into two lamellæ, one of which passes in front of the Rectus, to blend with the aponeurosis of the Obliquus externus, the other, behind it, blends with the aponeurosis of the Transversus, and these, joining again at the lateral border of the Rectus, are inserted into the linea alba. This arrangement of the aponeuroses exists from the costal margin to midway between the umbilicus and symphysis pubis, where the posterior wall of the sheath ends in a concave curved margin, the *linea semicircularis* (fig. 559), the concavity of which is directed downwards. In the upper part of the sheath muscular fibres of the Transversus extend into its posterior wall, and not infrequently do so

FIG. 558.—The interfoveolar ligament. Anterior aspect. (Modified from Braune.)

considerable extent (figs. 559, 560). Below the level of the linea semicircularis the aponeuroses of all three muscles pass in front of the Rectus; those of the Transversus and Obliquus internus are intimately fused together, the aponeurosis of the Obliquus externus is bound to them merely by loose connective tissue except in and near the middle line; behind, the Rectus is separated from the peritoneum by the transversalis fascia (fig. 561). Since the aponeuroses of the Obliquus internus and Transversus only reach as far as the costal margin, it follows that above this level the sheath of the Rectus is deficient posteriorly, the muscle resting directly on the cartilages of the ribs; the front of this part of the Rectus is covered merely by the tendon of the Obliquus externus.

Nerve-supply.—The Rectus abdominis is supplied by the anterior divisions of the lower thoracic nerves.

Actions.—The Rectus abdominis acting from above elevates the front of the pelvis; acting from below it depresses the thorax, and in continued action flexes the vertebral column. The two muscles are also powerful compressors of the abdominal viscera.

Applied Anatomy.—In suturing incisions through the upper part of the sheath of the Rectus abdominis it is necessary to suture the Transversus abdominis where it enters into the formation of the posterior wall of the sheath. The fibres of the Transversus abdominis being very pale, fine, and sometimes covered with a thin layer of fascia, are liable to be overlooked.

Pyramidalis (fig. 559) is a triangular muscle, placed at the lower part of abdomen, in front of the Rectus abdominis and within the sheath of that It arises by tendinous fibres from the front of the os pubis and from mentous fibres in front of the symphysis; the fleshy portion of the passes upwards, diminishing in size as it ascends, and ends in a pointed

559.—The right Rectus abdominis and the left Pyramidalis. The greater part of the left Rectus abdominis has been removed to show the superior and inferior epigastric vessels.

remity which is inserted into the linea alba midway between the umbilicus os pubis, but may extend to a higher level. This muscle may be larger one side than on the other, or may be wanting on one or both sides. Besides the Rectus and Pyramidalis, the sheath of the Rectus contains the superior inferior epigastric arteries, and the terminal portions of the lower intercostal nerves.

Nerve-supply.—The Pyramidalis is supplied by the twelfth thoracic nerve.

Action.—The Pyramidalis is a tensor of the linea alba.

The **linea alba** (fig. 559) is a tendinous band in the middle line of the stretching between the xiphoid process and the symphysis pubis. It is formed by the blending between the medial borders of the Recti, and is narrow below, broader above, aponeuroses of the Obliqui and Transversi. It is narrow below, corresponding to the linear interval existing between the Recti; but broader above, where these muscles diverge from one another. Its lower end has a double attachment—its superficial fibres passing in front of the medial heads of the Recti to the symphysis pubis, while its deeper fibres form a triangular lamella behind the Recti to the posterior surface of the crest of the os pubis, as the *adminiculum lineæ albæ*. The linea alba presents apertures for the passage of vessels and nerves; the umbilicus, which in the fœtus exists as an aperture and transmits the umbilical vessels, is closed a few days after birth.

Fig. 560.—A transverse section through the anterior abdominal wall, above the umbilicus. Diagrammatic.

The **lineæ semilunares** are two curved tendinous lines corresponding to the lateral borders of the Recti; each extends from the cartilage of the ninth rib to the pubic tubercle, and marks the line along which the aponeurosis of the Obliquus internus splits to enclose the Rectus abdominis.

The **transversalis fascia** is a thin membrane which lies between the inner surface of the Transversus muscle and the extraperitoneal fat. It is a part of the general layer of fascia lining the abdominal parietes, and is continuous with the iliac and pelvic fasciæ. In the inguinal region it is thin and dense in structure, and is joined by fibres from the aponeurosis of the Transversus, but it becomes thin as it ascends to the Diaphragm, and is lost with the fascia covering the under surface of this muscle. Behind, it is lost in the fat which covers the posterior surfaces of the kidneys. Below, it has the following attachments: posteriorly, to the whole length of the iliac crest

Fig. 561.—A transverse section through the anterior abdominal wall, below the linea semicircularis. Diagrammatic.

between the origins of the Transversus and Iliacus; between the anterior superior iliac spine and the femoral vessels it is connected to the posterior margin of the inguinal ligament, and is there continuous with the iliac fascia. Medial to the femoral vessels it is thin and is fixed to the pecten pubis, behind the inguinal aponeurotic falx, with which it is united; it descends in front of the femoral vessels to form the anterior wall of the femoral sheath. The spermatic cord in the male, and the round ligament of the uterus in the female, pass through the transversalis fascia at a spot called the *abdominal inguinal ring*. This opening is not visible externally since the transversalis fascia is prolonged on these structures as the infundibuliform fascia.

The **abdominal inguinal ring** (internal abdominal ring) is situated in the transversalis fascia, midway between the anterior superior iliac spine

mphysis pubis, and 1·25 cm. above the inguinal aponeurosis. It is of al form, the long axis of the oval being vertical; it varies in size rent subjects, and is much larger in the male than in the female. It is d above by the arched lower margin of the Transversus, and medially inferior epigastric vessels. It transmits the spermatic cord in the male e round ligament of the uterus in the female. From its circumference funnel-shaped membrane, the *infundibuliform fascia*, is continued as a ng on the spermatic cord and testis.

e inguinal canal contains the spermatic cord and the ilio-inguinal nerve male, and the round ligament of the uterus and the ilio-inguinal nerve in male. It is an oblique canal about 4 cm. long, slanting downwards and wards, and placed parallel with and a little above the inguinal ligament; nds from the abdominal inguinal ring to the subcutaneous inguinal ring. bounded *in front* by the integument, superficial fascia, and aponeurosis of bliquus externus throughout its whole length, and by the Obliquus internus lateral one-third; *behind* by the reflected inguinal ligament, the inguinal urotic falx, the transversalis fascia, the extraperitoneal connective tissue, e peritoneum; *above* by the arched fibres of the Obliquus internus and versus abdominis; *below* by the union of the transversalis fascia with uinal ligament, and at its medial end by the lacunar ligament.

extraperitoneal connective tissue.—Between the inner surface general layer of the fascia which lines the interior of the abdominal and cavities, and the peritoneum, there is a considerable amount of connec- tissue, termed the *extraperitoneal or subperitoneal connective tissue.* For tive purposes it may be divided into a parietal and a visceral portion. e *parietal* portion lines the cavity, and varies in quantity in different ions. It is especially abundant on the posterior wall of the abdomen, ticularly around the kidneys, where it contains much fat. It is scanty anterolateral wall of the abdomen, except in the pubic region and above crest; there is a considerable amount in the pelvis.

e *visceral* portion follows the course of the branches of the abdominal between the layers of the mesenteries and other folds of peritoneum connect the viscera to the abdominal and pelvic walls.

2. The Posterior Muscles of the Abdomen

Psoas major.	Iliacus.
Psoas minor.	Quadratus lumborum.

Psoas major, the Psoas minor, and the Iliacus, with the fasciæ covering re described with the muscles of the lower extremity (p. 530).

fascia covering the Quadratus lumborum is a thin layer attached, ly, to the bases of the transverse processes of the lumbar vertebræ; to the iliolumbar ligament; above, to the apex and lower border of the b. The upper margin of this fascia, which extends from the transverse s of the first lumbar vertebra to the apex and lower border of the last ssitutes the lateral lumbocostal arch (p. 465). Laterally, the fascia with the layer of the lumbodorsal fascia, which intervenes between adratus lumborum and the Sacrospinalis.

Quadratus lumborum (fig. 546, p. 459) is irregularly quadrilateral in and broader below than above. It arises by aponeurotic fibres from lumbar ligament and the adjacent portion of the iliac crest for about d is inserted into the lower border of the last rib for about one-half its and by four small tendons into the apices of the transverse processes upper four lumbar vertebræ. Occasionally a second portion of this is found in front of the preceding; it arises from the upper borders of nsverse processes of the lower three or four lumbar vertebræ, and is d into the lower margin of the last rib.

ront of the Quadratus lumborum are the colon, the kidney, the Psoas major , and the Diaphragm; between the fascia and the muscle are the twelfth , iliohypogastric, and ilio-inguinal nerves.

rve-supply.—The Quadratus lumborum is supplied by the anterior divisions twelfth thoracic and upper three or four lumbar nerves.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Actions.—The Quadratus lumborum draws down the last rib, and is a muscle of inspiration by helping to fix the origin of the Diaphragm. If the pelvis and vertebral column are fixed, it may act upon the pelvis, raising it on its own side when only one muscle is put in action; and when both muscles act either from below or above, they flex the trunk.

V. The Muscles of the Pelvis

Obturator internus.
Piriformis.

Levator ani.
Coccygeus.

The muscles within the pelvis may be divided into two groups: (1) the Piriformis and the Obturator internus, which are described with the muscles of the lower extremity (pp. 543, 544); (2) the Levator ani and the Coccygeus, which together form the *pelvic diaphragm* and are associated with the pelvic viscera. The classification of the two groups under a common heading is convenient in connexion with the fasciæ investing the muscles. These fasciæ are closely related to one another and to the deep fascia of the perineum, and in addition are connected with the fascial coverings of the pelvic viscera. It is customary therefore to describe them together under the term *pelvic fascia*.

Fig. 562.—A coronal section through the pelvis, showing the arrangement of the fasciæ. Posterior aspect. Diagrammatic.

Pelvic fascia.—The fascia of the pelvis may be resolved into: (A) the fascial sheaths of the Obturator internus, Piriformis, and pelvic diaphragm; (B) the fascial sheaths of the pelvic viscera (see section on Splanchnology).

The *fascia of the Obturator internus* covers the pelvic surface of the muscle, attached round the margin of the origin of, the muscle. Above, it is continuous with the posterior part of the arcuate line, and is there continuous with the iliac fascia. In front of this, as it follows the line of origin of the Obturator internus, it gradually separates from the iliac fascia, and the continuity between them is retained only through the periosteum. It arches beneath the obturator vessels and nerve, completing the obturator canal, and at the front of the canal is attached to the back of the superior ramus of the os pubis. The lower part of the obturator fascia forms the lateral wall of the ischiorectal fossa, and is attached inferiorly to the falciform process of the sacrotuberous ligament.

pubic arch; at the pubic arch it is continuous with the superior fascia urogenital diaphragm. Behind, it is prolonged into the glutæal region. internal pudendal vessels and pudendal nerve are placed in the lateral the ischiorectal fossa, and are enclosed in a special sheath of the fascia, Alcock's canal.

fascia of the Piriformis is very thin and is attached to the front of the around the margins of the anterior sacral foramina; it is prolonged on scle into the glutæal region. At its sacral attachment it comes into

563.—A median sagittal section through the pelvis, showing the arrangement of the fasciæ. Diagrammatic.

ate association with and ensheathes the nerves emerging from these mina; hence the sacral nerves are frequently described as lying behind the a. The internal iliac vessels and their branches, on the other hand, lie in subperitoneal tissue in front of the fascia, and the branches of these vessels the glutæal region emerge in special sheaths of this tissue, above and below Piriformis muscle.

The *diaphragmatic part of the pelvic fascia* (fig. 562) covers both surfaces of Levatores ani. That on the inferior surface of the muscle is very thin, and wn as the *anal fascia*; it forms the medial wall of the ischiorectal fossa, is attached above to the obturator fascia along the line of origin of the ator ani; it is continuous below with the superior fascia of the urogenital phragm, and with the fascia on the Sphincter ani externus. The layer ering the upper surface of the Levator ani follows, above, the line of origin the muscle, and is therefore somewhat variable. In front it is attached to

The **Levator ani** (fig. 564) is a broad, thin muscle; it is attached to the r surface of the side of the lesser pelvis, and unites with its fellow of the osite side to form the greater part of the floor of the pelvic cavity. It in front, from the pelvic surface of the superior ramus of the os pubis t to the symphysis; behind, from the inner surface of the spine of the ; and between these two points, from the obturator fascia. Posteriorly origin from the obturator fascia corresponds, more or less closely, with the tinous arch or white line of the pelvic fascia, but in front, the muscle arises the fascia at a varying distance above the arch, in some cases reaching ly as high as the canal for the obturator vessels and nerve. The fibres pass wards and backwards to the middle line of the floor of the pelvis; the erior fibres are inserted into the side of the last two segments of the coccyx into a median fibrous raphe (*anococcygeal raphe*), which extends between the yx and the margin of the anus. The middle fibres are inserted into the side e anal canal, blending with those of the Sphincter ani muscles; the anterior s descend upon the side of the prostate to unite beneath it with the muscle the opposite side, joining with the fibres of the Sphincter ani externus Transversus perinæi superficialis at the central tendinous point of the neum.

e anterior portion is occasionally separated from the rest of the muscle nnective tissue. From this circumstance, as well as from its peculiar on with the prostate, which it supports as in a sling, it has been described distinct muscle, under the name of *Levator prostatæ*. In the female the erior fibres of the Levator ani descend upon the side of the vagina.

e Levator ani may be divided into Iliococcygeus and Pubococcygeus.

e *Iliococcygeus* arises from the ischial spine and from the posterior part of the ten- arch of the pelvic fascia, and is attached to the coccyx and anococcygeal raphe; it lly thin, and may fail entirely or be largely replaced by fibrous tissue. An acces- lip at its posterior part is sometimes named the *Iliosacralis*. The *Pubococcygeus* from the back of the os pubis and from the anterior part of the obturator fascia, and ted backwards almost horizontally along the side of the anal canal. Between the x and the anal canal the Pubococcygei come together and form a thick, fibro- ular layer lying on the raphe formed by the Iliococcygei. The fibres which form a for the rectum are named the *Puborectalis* or *Sphincter recti*; they rise from ower part of the symphysis pubis, and from the superior fascia of the urogenital ragm; they meet with the corresponding fibres of the opposite side around the lower of the rectum, and form for it a strong sling.

Symington* suggests that the Pubococcygeus should be named *Pubo-analis*, as it is ntil if any of its fibres reach the coccyx.

Relations.—The *upper or pelvic surface* of the Levator ani is in relation with the agmatic part of the pelvic fascia which separates it from the bladder, prostate, m, and peritoneum. Its *lower or perinæal surface* forms the medial boundary of the ectal fossa, and is covered by the inferior layer of the diaphragmatic part of the fascia (*anal fascia*). Its *posterior border* is free and separated from the Coccygeus by areolar tissue. Its *anterior border* is separated from the muscle of the opposite by a triangular space, through which the urethra, and in the female the urethra and , pass from the pelvic.

Nerve-supply.—The Levator ani is supplied by a branch from the fourth sacral ve and by a branch which arises either from the perinæal, or from the inferior orrhoidal, division of the pudendal nerve.

Actions.—The Levatores ani constrict the lower end of the rectum and vagina. ther with the Coccygei they form a muscular diaphragm which supports the e viscera.

The **Coccygeus** (fig. 561) is situated behind the Levator ani. It is a trian- r plane of muscular and tendinous fibres, arising by its apex from the e of the ischium and from the sacrospinous ligament, and inserted by its s into the margin of the coccyx and into the side of the lowest piece of acrum. It assists the Levator ani and Piriformis in closing the posterior of the outlet of the pelvic.

Nerve-supply.—The Coccygeus is supplied by a branch from the fourth and sacral nerves.

Actions.—The Coccygei pull forward and support the coccyx, after it has been ed backwards during defæcation or parturition.

* *Journal of Anatomy and Physiology*, vol. xxiii.

Applied Anatomy.—Injury to the muscles forming the pelvic diaphragm occ infrequently during parturition. Where the damage is considerable or in cases muscles are weak the Levatores ani fail to act as efficient supports and prol uterus results; in severe cases the ovaries, bladder and rectum may also prolap

VI. The Muscles of the Perinæum

The perinæum corresponds to the outlet of the pelvis. Its deep b are—in front, the pubic arch and the arcuate pubic ligament; be tip of the coccyx; and on either side the inferior rami of the os p ischium, the ischial tuberosity, and the sacrotuberous ligament. T is somewhat lozenge-shaped and is limited on the surface of the body scrotum in front, by the buttocks behind, and by the medial sid thighs laterally. A line drawn transversely in front of the ischial tub divides the space into two portions. The posterior contains the term of the anal canal, and is known as the *anal region*; the anterior the external urogenital organs, and is termed the *urogenital region*.

The muscles of the perinæum may therefore be divided into two gr

1. Those of the anal region.
2. Those of the urogenital region: A, In the male; B, In the f

1. The Muscles of the Anal Region

Corrugator cutis ani. Sphincter ani externus. Sphincter ani int

The **superficial fascia** is very thick, areolar in texture, and contai fat in its meshes. On either side a pad of fatty tissue extends deeply b the Levator ani and Obturator internus into a space known as the is *fossa*.

The **deep fascia** forms the lining of the ischiorectal fossa; it co the anal fascia, and the portion of obturator fascia below the co Levator ani.

Ischiorectal fossa.—The fossa is somewhat prismoid in shape, with i directed to the surface of the perinæum, and its apex at the line of u of the obturator and anal fasciæ. It is bounded medially by the Sp ani externus and the anal fascia; laterally, by the tuberosity of the is and the obturator fascia; anteriorly, by the fascia of Colles coverin Transversus perinæi superficialis, and by the fascia of the urogenital diaph posteriorly, by the Glutæus maximus and the sacrotuberous ligament. Cr the space transversely are the inferior hæmorrhoidal vessels and nerve the posterior part are the perinæal and perforating cutaneous bran the pudendal plexus; while from the anterior part the posterior scro labial) vessels and nerves emerge. The internal pudendal vessels and pu nerve lie on the lateral wall of the fossa, in Alcock's canal (p. 483). Th is filled with fatty tissue, across which numerous fibrous bands extend.

Applied Anatomy.—Abscess in the ischiorectal fossa commonly occurs; it may at the side of the anus, at the border of Glutæus maximus, or against the rectal wall. is great pain on defæcation. On examining the bowel, fullness on the side of the may be detected. If left to itself the pus will find exit through the skin, or into t canal between the two Sphincters; and the condition will degenerate into one varieties of fistula, owing to the Sphincter ani externus closing the outlet of the and so causing the pus to track and burrow widely into the soft fat in the fossa, a in the subcutaneous tissues. To open an ischiorectal abscess an incision should be tangential to the anus over the region of the ischiorectal fossa, and should then verted into a T, by making a second incision laterally at right angles to it, so th wound may be kept open and may heal up from the bottom. Frequently, how spite of care, a fistula ensues which requires division of the Sphincter ani externus cure.

The **Corrugator cutis ani.**—Around the anus is a thin stratum of in tary muscular fibres which radiate from the anal orifice. Medially the fade off into the submucous tissue; laterally they blend with the tru When the muscle contracts the skin around the anus is raised into ridge

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Sphincter ani externus** (figs. 565, 567) is a flat sheet of muscular elliptical in shape and intimately adherent to the skin surrounding the It measures from 8 to 10 cm. in length and is about 2·5 cm. in width site the anus. It consists of two portions, superficial and deep. The *ficial portion* constitutes the chief part of the muscle, and arises from a ow tendinous band, the *anococcygeal raphe*, which stretches from the tip he coccyx to the posterior margin of the anus; it forms two flattened s of muscular tissue, which encircle the anus and meet in front to be inserted the central tendinous point of the perinæum, joining with the Transversus ni superficialis, the Levator ani, and the Bulbocavernosus. The *deep* ion forms a complete sphincter to the anal canal. Its fibres surround canal, closely applied to the Sphincter ani internus, and in front blend the other muscles at the central point of the perinæum. In a considerable portion of cases the fibres decussate in front of the anus, and are continuous the Transversi perinæi superficiales. Posteriorly, they are not attached he coccyx, but are continuous with those of the opposite side behind the canal. The upper edge of the muscle is ill-defined, since fibres are given from it to join the Levator ani.

Nerve-supply.—The Sphincter ani externus is supplied by a branch from the sacral nerve and by twigs from the inferior hæmorrhoidal branch of the dal nerve.

Actions.—The action of the Sphincter ani externus is peculiar. 1. It is normally state of tonic contraction, and having no antagonistic muscle it keeps the anal and orifice closed. 2. It can be put into a condition of greater contraction under fluence of the will, so as more firmly to occlude the anal aperture. 3. Taking xed point at the coccyx, it helps to fix the central point of the perinæum.

The **Sphincter ani internus** is a muscular ring which surrounds about m. of the anal canal; its inferior border is in contact with, but distinct the Sphincter ani externus. It is about 5 mm. thick, and is formed by aggregation of the involuntary circular fibres of the intestine. Its lower r is about 6 mm. from the orifice of the anus.

Actions.—Its action is entirely involuntary. It helps the Sphincter ani externus clude the anal aperture.

THE MUSCLES OF THE UROGENITAL REGION IN THE MALE (fig. 565)

Transversus perinæi superficialis. Ischiocavernosus.
Bulbocavernosus. Transversus perinæi profundus.
Sphincter urethræ membranaceæ.

The **superficial fascia** of this region consists of two layers, superficial deep.

The *superficial layer* is thick, loose, areolar in texture, and contains a variable nt of fat in its meshes. In front, it is continuous with the dartos tunic he scrotum; behind, with the subcutaneous areolar tissue surrounding anus; and, on either side, with the same fascia on the medial sides of the s. In the middle line, it is adherent to the skin and to the deep layer he superficial fascia.

The *deep layer of superficial fascia* (fascia of Colles) (fig. 563) is thin, apo-tic in structure, and of considerable strength, serving to bind down the les of the root of the penis. It is continuous, in front, with the dartos the deep fascia of the penis, the fascia of the spermatic cord, and Scarpa's upon the anterior wall of the abdomen; on either side it is attached to margins of the rami of the os pubis and ischium, lateral to the crus penis as far back as the tuberosity of the ischium; posteriorly, it curves round Transversi perinæi superficiales to join the posterior margin of the inferior a of the urogenital diaphragm. In the middle line, it is connected with superficial fascia and with the median septum of the Bulbocavernosus. s posterior part this fascia sends upwards from its deep surface a median um which incompletely divides the posterior portion of the subjacent space.

The central tendinous point of the perinæum.—This is a fibrous point in middle line of the perinæum, about 1·25 cm. in front of the anus, and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

close to the urethral bulb. Towards this point six muscles converge, are attached: viz. the Sphincter ani externus, the Bulbocavernosus, the two Transversi perinæi superficiales, and the anterior fibres of the Levatores ani.

The **Transversus perinæi superficialis** is a narrow muscular slip which passes more or less transversely across the perinæal space in front of the anus. It is often feebly developed, and is sometimes absent. It arises by a

Fig. 565.—The muscles of the male perinæum.

fibres from the medial and anterior part of the tuberosity of the ischium, running medialwards, is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, the Sphincter ani externus behind, and with the Bulbocavernosus in front. In some cases, the fibres of the deeper layer of the Sphincter ani externus decussate in front of the anus and are continued into this muscle. Occasionally it gives off fibres which join with the Bulbocavernosus of the same side.

Nerve-supply.—The Transversus perinæi superficialis is supplied by the perineal branch of the pudendal nerve.

Action.—The simultaneous contraction of the two Transversi perinæi superficiales serves to fix the central tendinous point of the perinæum.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

The **Bulbocavernosus** (Ejaculator urinæ) is placed in the middle line of the
næum, in front of the anus, and consists of two symmetrical parts, united
a median tendinous raphe. It arises from this median raphe and the central
dinous point of the perinæum. Its fibres diverge like the barbs of a quill-
, the most posterior form a thin layer, which is lost on the inferior fascia
he urogenital diaphragm; the middle fibres encircle the bulb and adjacent
ts of the corpus cavernosum urethræ, and are inserted into a strong
neurosis on the upper part of the corpus cavernosum urethræ; the anterior
ws spread out over the side of the corpus cavernosum penis, to be inserted
ly into that body, anterior to the Ischiocavernosus, and partly into a
dinous expansion which covers the dorsal vessels of the penis.

Nerve-supply.—The Bulbocavernosus is supplied by the perinæal branch of the
endal nerve.

Actions.—The Bulbocavernosus serves to empty the canal of the urethra, after
bladder has expelled its contents; during the greater part of the act of micturition
fibres are relaxed, and they only come into action at the end of the process.
e middle fibres are supposed by Krause to assist in the erection of the corpus
vernosum urethræ, by compressing the erectile tissue of the bulb. The anterior
es, according to Tyrrel, also contribute to the erection of the penis by compressing
deep dorsal vein of the penis, as their tendinous expansion is inserted into, and
ntinuous with, the fascia of the penis.

The **Ischiocavernosus** (Erector penis) covers the crus penis. It arises
tendinous and fleshy fibres from the inner surface of the tuberosity of the
hium, behind the crus penis; and from the inferior ramus of the ischium
either side of the crus. The muscular fibres end in an aponeurosis which
serted into the sides and under surface of the crus penis.

Nerve-supply.—The Ischiocavernosus is supplied by the perinæal branch of the
endal nerve.

Action.—The Ischiocavernosus compresses the crus penis, and retards the return
the blood through the veins, and thus serves to maintain the penis erect.

Between the muscles just examined a triangular space exists, bounded medially
the Bulbocavernosus, laterally by the Ischiocavernosus, and behind by the
nsversus perinæi superficialis; the floor is formed by the inferior fascia of
urogenital diaphragm. Running from behind forwards in the space are the
erior scrotal vessels and nerves, and the perinæal branch of the posterior femoral
taneous nerve; the transverse perinæal artery courses along its posterior boundary
the Transversus perinæi superficialis.

The deep **fascia** of the urogenital region forms an investment for the
nsversus perinæi profundus and the Sphincter urethræ membranaceæ, but
hin it there are also the deep vessels and nerves of this part, the whole forming
ansverse septum which is known as the *urogenital diaphragm*. From its
pe this part of the deep fascia is sometimes termed the *triangular ligament*,
d it is stretched almost horizontally across the pubic arch, so as to close the
erior part of the pelvic outlet. It consists of two membranous laminæ
. 566), which are united at the free edges of the muscles. The stronger and
re superficial of these laminæ is named the *inferior fascia of the urogenital*
phragm (superficial layer of the triangular ligament). Its base, directed
kwards, is connected to the central tendinous point of the perinæum and is
ntinuous with the anal fascia, and, behind the Transversus perinæi super-
ialis, with the deep layer of the superficial fascia. Its lateral margins are
ached to the inferior rami of the os pubis and ischium, above the crus
nis. Its apex, directed forwards is thickened to form the *transverse ligament*
the pelvis; between this ligament and the arcuate pubic ligament the deep
rsal vein of the penis (or clitoris) enters the pelvis. It is perforated, from
to 3 cm. below the symphysis pubis, by the urethra, the aperture for which
rcular and about 6 mm. in diameter; by the arteries and nerves to the
b and the ducts of the bulbo-urethral glands close to the urethra; by
deep arteries of the penis, one on either side close to the pubic arch and
ut halfway along the attached margin of the fascia; by the dorsal arteries
d nerves of the penis near the apex of the fascia. Its base is also perforated
the posterior scrotal vessels and nerves, while between its apex and the
uate pubic ligament the deep dorsal vein of the penis passes upwards into
e pelvis.

If the inferior fascia of the urogenital diaphragm be detached, the fo structures will be seen between it and the superior fascia: the membr portion of the urethra, the Transversus perinæi profundus and S urethræ membranaceæ, the bulbo-urethral glands and their ducts, the vessels and dorsal nerves of the penis, the arteries and nerves of the bulb, and a plexus of veins.

FIG. 566.—A coronal section through the anterior part of the pelvis. Anterior aspect. Diagrammatic.

The *superior fascia of the urogenital diaphragm* (deep layer of the trian ligament) is continuous with the obturator fascia and stretches across the arch. If the obturator fascia be traced medialwards after leaving the Obtu internus muscle, it will be found attached by some of its anterior fibre the inner margin of the pubic arch, while its posterior fibres pass over attachment to become continuous with the superior fascia of the urog diaphragm. Behind, this layer of the fascia blends with the inferior of the urogenital diaphragm and with the fascia of Colles; in front it is tinuous with the fascial sheath of the prostate, and is fused with the in fascia.

The **Transversus perinæi profundus** arises from the inferior ra the ischium and runs to the median line, where it interlaces in a tend raphe with its fellow of the opposite side. It lies in the same plane as Sphincter urethræ membranaceæ; formerly the two muscles were desc together as the *Constrictor urethræ*.

Nerve-supply.—The Transversus perinæi profundus is supplied by the pe branch of the pudendal nerve.

Action.—The Transversus perinæi profundus is a tensor of the central p the perinæum.

The **Sphincter urethræ membranaceæ** surrounds the membr portion of the urethra, and is enclosed in the fascia of the urogenital phragm. Its *external* fibres arise from the junction of the inferior rami os pubis and ischium, to the extent of 1·25 or 2 cm., and from the neighb fasciæ. They arch across the front of the urethra and bulbo-urethral gl pass round the urethra, and behind it unite with the muscle of the opp side, by means of a tendinous raphe. Its *innermost* fibres form a contin circular investment for the membranous urethra.

Nerve-supply.—The Sphincter urethræ membranaceæ is supplied by the perinæal branch of the pudendal nerve.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During micturition they, like the Bulbocavernosus, are relaxed, and only come into action at the end of the process to expel the last drops of urine.

The Muscles of the Urogenital Region in the Female (fig. 567)

Transversus perinæi superficialis. Ischiocavernosus.
Bulbocavernosus. Transversus perinæi profundus.
Sphincter urethræ membranaceæ.

The **Transversus perinæi superficialis** in the female is a narrow muscular which arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, the Sphincter ani externus behind, and the Bulbocavernosus in front.

Fig. 567.—The muscles of the female perinæum. (Modified from a drawing by Peter Thompson.)

Nerve-supply.—The Transversus perinæi superficialis is supplied by the perinæal branch of the pudendal nerve.

Action.—The simultaneous contraction of the two Transversi perinæi superficiales serves to fix the central tendinous point of the perinæum.

The **Bulbocavernosus** (Sphincter vaginæ) surrounds the orifice of the vagina. It covers the lateral parts of the vestibular bulbs, and is attached posteriorly to the central tendinous point of the perinæum, where it blends with the Sphincter ani externus. Its fibres pass forwards on either side of the vagina, to be inserted into the corpora cavernosa clitoridis, a fasciculus crossing over the body of the clitoris so as to compress the deep dorsal vein.

Actions.—The Ischiocavernosus compresses the crus clitoridis and re return of blood through the veins, and thus serves to maintain the clitori

The *fascia of the urogenital diaphragm* in the female is weaker tha the male, and is divided by the aperture of the vagina, with the exter of which it blends. As in the male, it consists of two layers; betwe are the following structures: a portion of the urethra, the Transversus p profundus and Sphincter urethræ membranaceæ muscles, the greater v glands and their ducts, the internal pudendal vessels, the dorsal nerve clitoris, the arteries and nerves of the bulbi vestibuli, and a plexus of ischium and runs across to the side of the vagina.

The **Transversus perinæi profundus** arises from the inferior ram

Nerve-supply.—The Transversus perinæi profundus is supplied by the branch of the pudendal nerve.

Action.—The Transversus perinæi profundus helps to fix the central te point of the perinæum.

The **Sphincter urethræ membranaceæ**, like the corresponding m the male, consists of external and internal fibres. The *external* fibres either side from the margin of the inferior ramus of the os pubis. T directed across the pubic arch in front of the urethra, and pass rou blend with the muscular fibres of the opposite side, between the ure vagina. The *innermost* fibres encircle the lower end of the urethra.

Nerve-supply.—The Sphincter urethræ membranaceæ is supplied perinæal branch of the pudendal nerve.

Actions.—The muscles of the two sides act as a constrictor of the ure slightly of the vagina.

THE FASCIÆ AND MUSCLES OF THE UPPER EXTREMI

The muscles of the upper extremity are divisible into the following g

I. Muscles connecting the upper extremity with the vertebral column.
II. Muscles connecting the upper extremity with the anterior and thoracic walls.
III. Muscles of the shoulder.
IV. Muscles of the arm.
V. Muscles of the forearm.
VI. Muscles of the hand.

I. The Muscles connecting the Upper Extremity with the Verte Column

Trapezius.
Latissimus dorsi.
Rhomboideus major.
Rhomboideus minor.
Levator scapulæ.

The **superficial fascia** of the back forms a layer of considerable thi and strength, and contains a quantity of granular fat. It is continuou the general superficial fascia.

The deep fascia is a dense fibrous layer, attached above to the superior nal line of the occipital bone; in the middle line it is fixed to the ligamentum ve and supraspinal ligament, and to the spinous processes of all the vertebræ the seventh cervical; laterally, in the neck it is continuous with the colli; over the shoulder it is attached to the spine of the scapula and to acromion, and is continued downwards over the Deltoideus to the arm; on thorax it is continuous with the deep fascia of the axilla and chest, and the abdomen with that covering the abdominal muscles; below, it is attached the crest of the ilium.

The Trapezius (fig. 568) is a flat, triangular muscle, covering the back of neck and shoulder. It arises from the medial one-third of the superior nal line of the occipital bone, the external occipital protuberance, the mentum nuchæ, the spinous process of the seventh cervical, and the spinous esses of all the thoracic vertebræ, and the corresponding portion of the raspinal ligament. The superior fibres proceed downwards and lateralwards, inferior upwards and lateralwards, and the middle horizontally; the superior s are inserted into the posterior border of the lateral one-third of the cle; the middle fibres into the medial margin of the acromion and the erior lip of the posterior border of the spine of the scapula; the inferior converge and end in an aponeurosis, which glides over the smooth tri- ar surface on the medial end of the spine of the scapula, and is inserted a tubercle at the apex of this smooth triangular surface. The upper of the Trapezius is connected to the occipital bone by a thin fibrous lamina, y adherent to the skin; the middle part arises by a broad semi-elliptical neurosis, which reaches from the sixth cervical to the third thoracic vertebra; lower part arises by short tendinous fibres. The two Trapezius muscles ether resemble a trapezium, or quadrangle; two angles corresponding the shoulders; a third to the occipital protuberance; and the fourth to spinous process of the twelfth thoracic vertebra.*

The clavicular insertion of this muscle varies in extent; it sometimes hes as far as the middle of the clavicle, and occasionally blends with or rlaps the posterior edge of the Sternocleidomastoideus.

Nerve-supply.—The Trapezius is supplied by the accessory nerve and by hes from the third and fourth cervical nerves.

Actions.—The Trapezius retracts the scapula and braces back the shoulders. If head be fixed the upper fibres elevate the point of the shoulder; the middle and er fibres rotate the scapula so as to raise the point of the shoulder. When the ulder is fixed the Trapezius draws the head backwards and lateralwards.

The Latissimus dorsi (fig. 568) is a large triangular, flat muscle, which ys the lumbar region and the lower one-half of the thoracic region; but its converge to a narrow tendon of insertion. It arises by tendinous fibres the spinous processes of the lower six thoracic vertebræ in front of the rzius, and from the posterior layer of the lumbodorsal fascia (p. 457), by h it is attached to the spines of the lumbar and sacral vertebræ, to the raspinal ligament, and to the posterior part of the crest of the ilium. In ition, it arises by muscular fibres from the external lip of the crest of the m lateral to the margin of the Sacrospinalis, and from the three or four er ribs by fleshy digitations which are interposed between similar processes the Obliquus abdominis externus (fig. 550). From this extensive origin e fibres pass in different directions, the upper ones horizontally, the middle ewhat upwards, and the lower almost vertically upwards, so as to converge d form a thick fasciculus, the upper part of which crosses, and usually ives a few fibres from, the inferior angle of the scapula. The muscle ses around the lower border of the Teres major, and is twisted upon itself, that the superior fibres become at first posterior and then inferior, and the ending fibres at first anterior and then superior. It ends in a quadrilateral ion, about 7 cm. long, which passes in front of the tendon of the Teres r, and is inserted into the bottom of the intertubercular sulcus of the erus, giving an expansion to the deep fascia of the arm; its insertion ends higher on the humerus than that of the tendon of the Pectoralis major. lower border of its tendon is united with that of the Teres major, the

* The two muscles cover the back of the neck and shoulders like a monk's cowl, and therefore Trapezius is sometimes termed the *Musculus cucullaris*.

surfaces of the two tendons being separated near their insertions by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula.

A muscular slip, the *axillary arch*, varying from 7 to 10 cm. in length, and from 5 to 2 mm. in breadth, occasionally springs from the upper edge of the Latissimus dorsi near the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coracobrachialis, or the fascia over the Biceps brachii. This axillary arch crosses the axillary artery, just above the spot usually selected for the application of a tourniquet, and may mislead the surgeon during the operation. It is present in about seven per cent. of subjects and may be easily recognised by the direction of its fibres.

A fibrous slip usually passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps brachii. This is occasionally muscular, and is the representative of the *Dorso-epitrochlearis brachii* of apes.

Nerve-supply.—The Latissimus dorsi is supplied by the sixth, seventh and eighth cervical nerves through the thoracodorsal (long subscapular) nerve.

Actions.—The Latissimus dorsi depresses the humerus, draws it backwards, and rotates it inwards. If the arm be fixed, the muscle may elevate the lower ribs in forced inspiration; when both arms are fixed it helps to pull the trunk upwards and forwards as in climbing.

The lower part of the lateral margin of the Latissimus dorsi is separated from the posterior free border of the Obliquus externus abdominis by a small triangular interval, the *lumbar triangle* (of Petit), the base of which is formed by the iliac crest, and its floor by the Obliquus internus abdominis (fig. 568). Another triangle, known as the *triangle of auscultation*, is situated behind the scapula. It is bounded above by the Trapezius, below by the Latissimus dorsi, and laterally by the vertebral border of the scapula; the floor is partly formed by the Rhomboideus major. If the scapula be drawn forwards by folding the arms across the chest, and the trunk bent forwards, parts of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation of the lung.

The **Rhomboideus major** (fig. 568) arises by tendinous fibres from the spinous processes of the second, third, fourth, and fifth thoracic vertebræ and the supraspinal ligament. The fibres of the muscle are directed downwards and lateralwards and are inserted into the vertebral border of the scapula between the triangular surface of the root of the spine and the inferior angle. Usually the insertion is an indirect one, the muscular fibres ending in a tendinous band which is fixed at its ends to the two points mentioned and joined to the vertebral border by a thin membrane; occasionally the arch is incomplete, and some of the muscular fibres are then inserted directly into the scapula.

Nerve-supply.—The Rhomboideus major is supplied by the fifth cervical through the dorsal scapular nerve.

Actions.—The Rhomboideus major retracts the scapula, and rotates it so that the inferior angle is carried backwards and upwards.

The **Rhomboideus minor** (fig. 568) arises from the lower part of the ligamentum nuchæ and from the spinous processes of the seventh cervical and first thoracic vertebræ; it is inserted into the base of the triangular smooth surface at the root of the spine of the scapula. It is usually separated from the Rhomboideus major by a slight interval, but the adjacent margins of the two muscles are occasionally united.

Nerve-supply.—The Rhomboideus minor is supplied by the fifth cervical nerve through the dorsal scapular nerve.

Action.—The Rhomboideus minor draws the scapula backwards, upwards and medialwards.

The **Levator scapulæ** (fig. 568) is situated at the back and side of the neck. It arises by tendinous slips from the transverse processes of the atlas and epistropheus and from the posterior tubercles of the transverse processes of the third and fourth cervical vertebræ. It is inserted into the vertebral border of the scapula, between the medial angle and the triangular smooth surface at the root of the spine.

Nerve-supply.—The Levator scapulæ is supplied directly by branches from the third and fourth cervical nerves, and by a branch from the fifth cervical nerve through the dorsal scapular nerve.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Actions.—If the cervical part of the vertebral column be fixed, the L. scapulæ raises the medial angle of the scapula; this produces a rotation of scapula by which the point of the shoulder is depressed. If the shoulder be f the muscle inclines the neck to the same side.

II. The Muscles connecting the Upper Extremity with the Anter and Lateral Thoracic Walls

Pectoralis major.	Subclavius.
Pectoralis minor.	Serratus anterior.

The **superficial fascia** of the anterior thoracic region is continuous w that of the neck and upper extremity above, and of the abdomen below encloses the mamma and gives off numerous septa which pass into the gla support its various lobes. From the fascia over the front of the mamma, fib processes pass forwards to the integument and mammary papilla; these called by Sir A. Cooper the *ligamenta suspensoria.*

The **pectoral fascia** is a thin lamina, covering the surface of the Pecto major, and sending numerous prolongations between its fasciculi; it is attach in the middle line, to the front of the sternum; above, to the clavicle; late and below, it is continuous with the fascia of the shoulder, axilla, and tho It is very thin over the upper part of the Pectoralis major, but thicker in interval between it and the Latissimus dorsi, where it closes in the axil space and forms the *axillary fascia*; this divides at the lateral margin of Latissimus dorsi into two layers, one of which passes in front of, and the o behind this muscle; these proceed as far as the spinous processes of the thor vertebræ, to which they are attached. As the fascia leaves the lower edge the Pectoralis major to cross the floor of the axilla it sends a layer upwa under cover of the muscle; this lamina splits to envelop the Pectoralis min and at the upper edge of this muscle is continuous with the coracoclavic fascia. The hollow of the armpit, seen when the arm is abducted, is produ mainly by the traction of this fascia on the axillary floor, and hence the lam is sometimes named the *suspensory ligament* of the axilla. At the lower p of the thoracic region the deep fascia is well developed, and is continuous w the fibrous sheath of the Rectus abdominis.

Applied Anatomy.—In cases of suppuration in the axilla, the pus is prevented fr extending downwards by the axillary fascia, and therefore tends to spread upwar beneath the pectoral muscles, towards the root of the neck. Early evacuation of the p is therefore necessary. The incision should be made midway between the anterior a posterior axillary folds, so as to avoid the lateral thoracic and subscapular vessels, a the edge of the knife should be directed away from the axillary vessels.

The **Pectoralis major** (fig. 569) is a thick, triangular muscle situated o the upper and front part of the chest. It arises from the anterior surface o the sternal half of the clavicle; from half the breadth of the anterior surfac of the sternum, as low down as the attachment of the cartilage of the sixth o seventh rib; from the cartilages of all the true ribs, with the exceptio frequently, of the first, or seventh, or both, and from the aponeurosis of th Obliquus externus abdominis. From this extensive origin the fibres converg towards their insertion; those arising from the clavicle pass obliquely down wards and lateralwards, and are usually separated from the rest by a sligh interval; those from the lower part of the sternum, and the cartilages of th lower true ribs, run upwards and lateralwards; while the middle fibres pas horizontally. They all end in a flat tendon, about 5 cm. broad, which is inserte into the crest of the greater tubercle of the humerus. This tendon consis of two laminæ, placed one in front of the other, and usually blended togethe below. The anterior lamina, the thicker, receives the clavicular and th uppermost sternal fibres; they are inserted in the same order as that in which they arise: that is to say, the most lateral of the clavicular fibres are inserted at the upper part of the anterior lamina, and the uppermost sternal fibre to the lower part of the lamina, which extends as low as the tendon of th Deltoideus and joins with it. The posterior lamina of the tendon receive

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

attachment of the greater part of the sternal portion and the deep fibres, those from the costal cartilages. These deep fibres, and particularly those the lower costal cartilages, turn backwards successively behind and a higher level than the superficial and upper ones, so that the tendon ars to be twisted. The posterior lamina of the tendon reaches higher the humerus than the anterior, and gives off an expansion which covers

FIG. 569.—The superficial muscles of the front of the chest and arm. Left side.

the intertubercular sulcus and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the intertubercular sulcus, while from the lower border of the tendon a third expansion passes downwards to the fascia of the arm.

Relations.—In front of the Pectoralis major are the skin, superficial fascia, Platysma, anterior and middle supraclavicular nerves, mamma, and deep fascia; its *posterior surface* is in contact with the sternum, ribs and costal cartilages, coracoclavicular fascia, subclavius, Pectoralis minor, Serratus anterior, and Intercostales; it forms the anterior wall of the axillary space, and covers the axillary vessels and nerves and the upper parts of the Biceps brachii and Coracobrachialis. Its *upper border* is separated from the deltoideus by a slight interspace—the *deltoid* or *clavicular triangle*, or *infraclavicular fossa*,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in which the cephalic vein and deltoid branch of the thoraco-acromial artery lie; *lower border* forms the anterior fold of the axilla; it is separated from the latissimus dorsi by a considerable interval at the medial wall of the axilla, but the two muscles gradually converge towards the lateral wall of the space.

Nerve-supply.—The Pectoralis major is supplied by the medial and lateral anterior thoracic nerves; through these it receives filaments from all the nerves entering into the formation of the brachial plexus; the fibres for the clavicular part of the muscle are derived from the fifth and sixth cervical nerves.

Actions.—The Pectoralis major adducts the arm. If the arm be flexed the muscle draws it forwards across the front of the chest and rotates it inwards. When the arms are fixed the Pectorales majores draw the trunk upwards and forwards in climbing.

The **coracoclavicular fascia** (costocoracoid membrane) is a strong fascia situated under cover of the clavicular portion of the Pectoralis major, and occupies the interval between the Pectoralis minor and Subclavius, and protects the axillary vessels and nerves. Traced upwards, it splits to enclose the Subclavius, and is attached to the clavicle, in front of and behind the muscle; the layer behind the muscle fuses with the fascia colli and with the sheath of the axillary vessels. Medially, the coracoclavicular fascia blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib medial to the origin of the Subclavius. Laterally, it is thick and dense and is attached to the coracoid process. The portion extending from the first rib to the coracoid process is often stronger than the rest, and is sometimes called the *costocoracoid ligament.* Below this, the fascia is thin; it splits to ensheathe the Pectoralis minor; and from the lower border of this muscle it is continued downwards to join the axillary fascia, and lateralwards to blend with the fascia covering the short head of the Biceps brachii. The coracoclavicular fascia is pierced by the cephalic vein, thoraco-acromial artery and vein, and lateral anterior thoracic nerve.

The **Pectoralis minor** (fig. 570) is a thin, triangular muscle, situated in the upper part of the thorax, deep to the Pectoralis major. It arises from the upper margins and outer surfaces of the third, fourth, and fifth ribs, near their cartilages, and from the aponeuroses covering the Intercostales externi; its fibres pass upwards and lateralwards, and converge to form a flat tendon, which is inserted into the medial border and upper surface of the coracoid process of the scapula. Sometimes a part or the whole of the tendon is continued over the coracoid process and through the coraco-acromial ligament; when this occurs the tendon blends with the coracohumeral ligament and thus gains attachment to the humerus.

Relations.—Its *anterior surface* is in relation with the Pectoralis major, the lateral anterior thoracic nerve, and the pectoral branch of the thoraco-acromial artery; its *posterior surface*, with the ribs, Intercostales externi, Serratus anterior, the axillary space, and the axillary vessels and brachial plexus of nerves. Its *upper border* is separated from the clavicle by a narrow triangular interval occupied by the coracoclavicular fascia, behind which are the axillary vessels and nerves. Running parallel with the *lower border* of the muscle is the lateral thoracic artery; piercing and partly supplying the muscle is the medial anterior thoracic nerve.

Nerve-supply.—The Pectoralis minor is supplied by the seventh and eighth cervical and first thoracic nerves through the anterior thoracic nerves.

Actions.—The Pectoralis minor depresses the scapula and rotates it by drawing the lateral angle downwards and forwards. When the arm is fixed it assists in elevating the ribs in forced inspiration.

The **Subclavius** (fig. 570) is a small triangular muscle, placed between the clavicle and first rib. It arises by a short, thick tendon from the junction of the first rib and first costal cartilage, in front of the costoclavicular ligament; the fleshy fibres proceed obliquely upwards and lateralwards, to be inserted into the groove on the under surface of the clavicle between the costoclavicular and coracoclavicular ligaments.

Relations.—Its *posterior surface* is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the coracoclavicular fascia, which, with the clavicle, forms an osseo-fibrous sheath for the muscle.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Nerve-supply.—The Subclavius is supplied by a branch which derives its fibres from the fifth and sixth cervical nerves.

Action.—The Subclavius pulls the shoulder downwards and forwards.

The **Serratus anterior** (Serratus magnus) (fig. 570) is a muscular sheet, situated between the ribs and scapula at the upper and lateral parts of the chest. It arises by fleshy slips or digitations from the outer surfaces and anterior borders of the upper eight or nine ribs, and from the aponeuroses covering the intervening Intercostales. Each digitation arises from the

FIG. 570.—The deep muscles of the front of the chest and arm. Left side.

responding rib, but the first springs in addition from the second rib, and from the fascia covering the first intercostal space. The lower four slips digitate with the upper five slips of the Obliquus externus abdominis. From this extensive attachment the fibres pass backwards, closely applied to the chest-wall, and are inserted into the ventral surface of the vertebral border of the scapula in the following manner. The first digitation is inserted into a triangular area on the ventral surface of the medial (superior) angle. The next two or three digitations spread out to form a thin, triangular sheet, the base of which is directed backwards and is inserted into nearly the whole length of the ventral surface of the vertebral border. The lower five or six digitations converge to form a fan-shaped mass, the apex of which is inserted, by muscular and tendinous fibres, into a triangular impression on the ventral surface of the inferior angle.

Nerve-supply.—The Serratus anterior is supplied by the long thoracic nerve, which is derived from the fifth, sixth, and seventh cervical nerves.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Actions.—The Serratus anterior, as a whole, carries the scapula forwards, at the same time raises the vertebral border of the bone. Its lower and stronger fibres move the lower angle forwards and assist the Trapezius in rotating the bone on the sternoclavicular joint, and thus aid this muscle in raising the acromion. It is also an assistant to the Deltoideus in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus moves. After the Deltoideus has raised the arm at a right angle with the trunk, the Serratus anterior and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position.

Applied Anatomy.—When the Serratus anterior is paralysed, the vertebral border, especially the lower angle of the scapula, leave the ribs and stand out prominently on the surface, giving a peculiar 'winged' appearance to the back (p. 279). The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the angle of the scapula from the back of the thorax.

The long thoracic nerve supplying the Serratus anterior is exposed in the operation for removal of cancer of the breast, and should always be carefully preserved.

III. The Muscles of the Shoulder

Deltoideus.	Infraspinatus.
Subscapularis.	Teres minor.
Supraspinatus.	Teres major.

The **deep fascia** covering the Deltoideus invests the muscle, and sends numerous septa between the fasciculi. In front, it is continuous with the pectoral fascia; behind, where it is thick and strong, with the fascia infraspinata; above, it is attached to the clavicle, the acromion, and the spine of the scapula; below, it is continuous with the brachial fascia.

The **Deltoideus** (fig. 569) is a thick, triangular muscle, which covers the shoulder-joint. It arises from the anterior border and upper surface of the lateral one-third of the clavicle; from the lateral margin and upper surface of the acromion, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its medial end. The fibres converge towards their insertion, the middle passing vertically, the anterior inclining backwards, and the posterior forwards; they unite in a thick tendon which is inserted into the deltoid tuberosity on the lateral side of the body of the humerus. At its insertion the tendon gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the part arising from the acromion consists of oblique fibres; these arise in a bipennate manner from the sides of tendinous septa, generally three in number, which pass downwards from the acromion into the muscle. The oblique fibres are inserted into similar tendinous septa, generally three in number, which ascend from the insertion of the muscle and alternate with the descending septa. The portions of the muscle arising from the clavicle and spine of the scapula are not arranged in this manner, but are inserted into the margins of the inferior tendon.

Relations.—Its *superficial surface* is in relation with the skin, the superficial and deep fasciæ, Platysma, posterior supraclavicular, and lateral brachial cutaneous nerves. Its *deep surface* is separated from the articular capsule of the shoulder-joint by a large bursa and covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coracobrachialis, both heads of the Biceps brachii, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the long and lateral heads of the Triceps brachii, the humeral circumflex vessels, the axillary nerve, and the surgical neck and upper part of the body of the humerus. Its *anterior border* is separated in its upper part from the Pectoralis major by the deltoideopectoral triangle in which the cephalic vein and deltoid branch of the thoraco-acromial artery lie; lower down the two muscles are in contact. Its *posterior border* rests on the Infraspinatus and Teres minor, brachii.

Nerves.—The Deltoideus is supplied by the fifth and sixth cervical nerves through the axillary nerve.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Actions.—The Deltoideus raises the arm from the side, so as to bring it at right angles with the trunk. Its anterior fibres draw the arm forwards; and its posterior fibres draw it backwards.

Applied Anatomy.—The Deltoideus is very liable to atrophy, and in this condition the prominence of the shoulder-joint is simulated, as there is flattening of the shoulder and prominence of the acromion; the distance also between the acromion and the head of the bone is increased, and the tips of the fingers can be inserted between them.

The **subscapular fascia** is a thin membrane attached to the entire circumference of the subscapular fossa, and giving origin by its deep surface to some of the fibres of the Subscapularis.

The **Subscapularis** (fig. 570) is a large triangular muscle which fills the subscapular fossa, and arises from its medial two-thirds and from the lower two-thirds of the groove on the axillary border of the scapula. Some fibres arise from tendinous laminæ which intersect the muscle and are attached to ridges on the bone; others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps brachii. The fibres pass laterally, and, gradually converging, end in a tendon which is inserted into the lesser tubercle of the humerus and the front of the capsule of the shoulder-joint. The tendon of the muscle is separated from the neck of the scapula by a large bursa, which communicates with the cavity of the shoulder-joint through an aperture in the articular capsule.

Relations.—The *anterior surface* of this muscle forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus anterior, Coracobrachialis, and Biceps brachii, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is in relation with the scapula and the capsule of the shoulder-joint. Its *lower border* is in contact with the Teres major and Latissimus dorsi.

Nerves.—The Subscapularis is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inwards; when the arm is raised, it draws the humerus forwards and downwards. It is a powerful defence to the front of the shoulder-joint.

The **fascia supraspinata** completes the osseofibrous case in which the supraspinatus muscle is contained, and its deep surface gives origin to some of the fibres of the muscle. It is thick medially, but thinner laterally under the coraco-acromial ligament.

The **Supraspinatus** (fig. 571) occupies the supraspinatous fossa, arising in its medial two-thirds, and from the fascia supraspinata. The muscular fibres pass under the acromion, and converge to a tendon which crosses the upper part of the shoulder-joint and is inserted into the highest of the three impressions on the greater tubercle of the humerus; the tendon is intimately adherent to the capsule of the shoulder-joint.

Nerve-supply.—The Supraspinatus is supplied by the fifth and sixth cervical nerves through the suprascapular nerve.

Action.—The Supraspinatus abducts the arm.

The **fascia infraspinata** is a dense fibrous membrane, covering the infraspinatus muscle and fixed to the circumference of the infraspinatous fossa; its deep surface gives origin to some fibres of that muscle. It is intimately attached to the deltoid fascia along the overlapping border of the Deltoideus.

The **Infraspinatus** (fig. 571) is a thick triangular muscle, which occupies the chief part of the infraspinatous fossa; it arises by fleshy fibres from the medial two-thirds of the fossa, and by tendinous fibres from the ridges on its surface: it also arises from the fascia infraspinata which covers it and separates it from the Teretes major et minor. The fibres converge to a tendon, which passes over the lateral border of the spine of the scapula, and, passing across the posterior part of the capsule of the shoulder-joint, is inserted into the middle impression on the greater tubercle of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a bursa which may communicate with the joint-cavity.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Nerve-supply.—The Infraspinatus is supplied by the fifth and sixth c nerves through the suprascapular nerve.

Action.—The Infraspinatus rotates the arm outwards.

The **Teres minor** (fig. 571) is a narrow, elongated muscle, which arise the dorsal surface of the axillary border of the scapula for the upper two of its extent, and from two aponeurotic laminæ, one of which separates the Infraspinatus, the other from the Teres major. Its fibres run ob upwards and lateralwards; the upper ones end in a tendon which is in into the lowest of the three impressions on the greater tubercle of the hu the lower fibres are inserted directly into the humerus immediately bel

impression and just above the origin of the lateral head of the Triceps bra The tendon of this muscle passes across, and is united with, the posterior p of the capsule of the shoulder-joint.

Nerve-supply.—The Teres minor is supplied by the fifth cervical nerve thro the axillary nerve.

Action.—The Teres minor rotates the arm outwards.

The **Teres major** (fig. 571) is a thick, somewhat flattened muscle, w arises from the oval area on the dorsal surface of the inferior angle of scapula, and from the fibrous septa interposed between the muscle a the Teres minor and Infraspinatus; the fibres are directed upwards a lateralwards and end in a flat tendon, about 5 cm. long, which is inser into the crest of the lesser tubercle of the humerus. At its insertion t tendon lies behind that of the Latissimus dorsi, from which it is separ by a bursa, the two tendons being, however, united along their lower bord for a short distance.

erve-supply.—The Teres major is supplied by the fifth and sixth cervical nerves ugh the lower subscapular nerve

ctions.—The Teres major draws the humerus medialwards and backwards, rotates it inwards.

IV. The Muscles of the Arm

Coracobrachialis.
Biceps brachii.
Brachialis.
Triceps brachii.

The **brachial fascia** or deep fascia of the arm is continuous with that ering the Deltoideus and the Pectoralis major; it forms a thin, loose sheath the muscles of the arm, and sends septa between them; it is composed bres disposed in a circular or spiral direction, and connected together vertical and oblique fibres. It is thin over the Biceps brachii, but thicker re it covers the Triceps brachii, and over the epicondyles of the humerus: strengthened by fibrous aponeuroses, derived from the Pectoralis major Latissimus dorsi medially, and from the Deltoideus laterally. On either gives off a strong intermuscular septum, which is attached to the ponding supracondylar ridge and epicondyle of the humerus.

The *lateral intermuscular septum* extends from the lower part of the crest the greater tubercle of the humerus, along the lateral supracondylar ridge, e epicondyle; it is blended with the tendon of the Deltoideus, gives ment to the Triceps brachii behind, to the Brachialis, Brachioradialis Extensor carpi radialis longus in front, and is perforated by the radial and arteria profunda brachii. The *medial intermuscular septum*, thicker the preceding, extends from the lower part of the crest of the lesser tubercle humerus below the Teres major, along the medial supracondylar ridge e epicondyle; it is blended with the tendon of the Coracobrachialis, and attachment to the Triceps brachii behind and the Brachialis in front. perforated by the ulnar nerve, the superior ulnar collateral artery, and posterior branch of the inferior ulnar collateral artery.

the elbow, the brachial fascia is attached to the epicondyles of the rus and the olecranon of the ulna, and is continuous with the antibrachial . Just below the middle of the medial side of the arm, an oval opening e fascia transmits the basilic vein and some lymphatic vessels.

The **Coracobrachialis** (figs. 570, 572) is situated at the upper and medial of the arm. It arises from the apex of the coracoid process, in common the tendon of the short head of the Biceps brachii, and by muscular fibres the upper 10 cm. of this tendon; it is inserted into an impression at middle of the medial surface and border of the body of the humerus between origins of the Triceps brachii and Brachialis.

elations.—It is perforated by the musculocutaneous nerve, and is in relation, in with the Pectoralis major above, and at its insertion with the brachial vessels and nerve which cross it; *behind*, with the tendons of the Subscapularis, Latissimus and Teres major, the medial head of the Triceps brachii, the humerus, and the r humeral circumflex vessels; by its *medial border*, with the third part of the y artery, the upper part of the brachial artery, the median and musculocutaneous ; by its *lateral border*, with the Biceps brachii and Brachialis.

erve-supply.—The Coracobrachialis is supplied by the seventh cervical nerve gh the musculocutaneous nerve.

ction.—The Coracobrachialis draws the arm forwards and medialwards.

The **Biceps brachii** (figs. 570, 572, 573), a long fusiform muscle placed on ont of the arm, has received its name from the circumstance that it has heads of origin. The *short head* arises by a thick flattened tendon from pex of the coracoid process, in common with the Coracobrachialis. The *head* arises by a long narrow tendon from the supraglenoid tuberosity at pex of the glenoid cavity, and is continuous with the glenoidal labrum). The tendon of the long head, enclosed in a sheath of the synovial m of the articular capsule of the shoulder-joint, arches over the head of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

humerus; it emerges from the joint through an opening in the articular capsule close to its humeral attachment and descends in the intertubercular groove; it is retained in the sulcus by the transverse humeral ligament and by a expansion from the tendon of the Pectoralis major. Each tendon is preceded by an elongated muscular belly, and the two bellies, although applied to each other, can be readily separated until within about 7 cm. of the elbow-joint. Here they end in a flattened tendon, which is inserted into the rough posterior portion of the tuberosity of the radius, a bursa being interposed between the tendon and the front part of the tuberosity. As the tendon of the muscle approaches the radius it is twisted upon itself, so that its medial surface becomes lateral and is applied to the tuberosity of the radius in its insertion. Opposite the bend of the elbow the tendon gives off, from its medial side, a broad aponeurosis, the *lacertus fibrosus* or *bicipital fascia*, which passes obliquely downwards and medialwards across the brachial artery and is continuous with the deep fascia covering the origins of the flexor muscles of the forearm (fig. 569). With very little force the tendon of insertion may be split down to the radial tuberosity, when it can be seen that the anterior portion of the tendon receives the fibres of the short head, and the posterior portion those of the long head.

Fig. 572.—A transverse section through the arm at the junction of the proximal with the intermediate one-third of the humerus.

A third head to the Biceps brachii is occasionally found, arising at the upper medial part of the Brachialis, with which it is blended, and inserted into the lacertus fibrosus and medial side of the tendon of the muscle; in most cases this additional head lies behind the brachial artery. In some instances the third head consists of two slips which pass down, one in front of, the other behind the artery.

Relations.—The Biceps brachii is overlapped above by the Pectoralis major and Deltoideus; in the rest of its extent it is covered by the fasciæ and skin. Above, its long head passes through the shoulder-joint, and its short head rests on the joint and the upper part of the humerus; below, it lies on the Brachialis, the musculocutaneous nerve, and the Supinator. Its *medial border* is in relation with the Coracobrachialis, and overlaps

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ial vessels and median nerve; its *lateral border*, with the Deltoideus and
hioradialis.

erve-supply.—The Biceps brachii is supplied by the fifth and sixth cervical
s through the musculocutaneous nerve.

ctions.—The Biceps brachii is a powerful supinator of the forearm; it also
the elbow-joint, and to a slight extent the shoulder-joint. Through the
us fibrosus it is a tensor of the antibrachial fascia.

pplied Anatomy.—The long tendon of the Biceps brachii is sometimes dislocated
the intertubercular sulcus. When this occurs, the arm is fixed in a position of
ction, but the head of the humerus can be felt in its proper position. The tendon
generally be replaced by flexing the forearm on the arm and rotating the limb.
ure of the long tendon of the Biceps brachii may also take place.

Fig. 573.—A transverse section through the arm, a little below the middle of the body of the humerus.

The **Brachialis** (Brachialis anticus) (figs. 570, 573, 574) covers the front
the elbow-joint and the lower one-half of the humerus. It arises from the
r one-half of the front of the humerus, commencing above at the insertion
the Deltoideus, which it embraces by two angular processes, and extending
r to within 2·5 cm. of the margin of the articular surface. It also arises
the intermuscular septa, but more extensively from the medial than the
al; it is separated from the lower part of the lateral intermuscular septum
the Brachioradialis and Extensor carpi radialis longus. Its fibres converge
thick tendon, which is inserted into the tuberosity of the ulna and the
h depression on the anterior surface of the coronoid process.

Relations.—It is in relation, in *front*, with the Biceps brachii, the brachial vessels,
ocutaneous and median nerves; *behind*, with the humerus and articular capsule
the elbow-joint; by its *medial border*, with the Pronator teres, and with the medial
muscular septum which separates it from the Triceps brachii and the ulnar nerve;
its *lateral border*, with the radial nerve, radial recurrent artery, the Brachioradialis,
Extensor carpi radialis longus.

Nerve-supply.—The Brachialis is chiefly supplied by the fifth and sixth cervical
es through the musculocutaneous nerve, but receives an additional filament
the seventh cervical through the radial nerve.

Action.—The Brachialis flexes the elbow-joint.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Triceps brachii** (figs. 571, 572, 573, 574), situated on the ba arm, is of large size, and arises by three heads (long, lateral, and medial its name.

The *long head* arises by a flattened tendon from the infraglenoid tu of the scapula, being blended at its upper part with the capsule of the joint; the muscular fibres pass downwards between the other two heads muscle, and join with them in the tendon of insertion.

The *lateral head* arises from a narrow ridge on the posterior surfa body of the humerus, extending from the insertion of the Teres minor upper part of the sulcus for the radial nerve, and from the lateral b the humerus and the lateral intermuscular septum; the fibres from th converge towards the tendon of insertion.

Fig. 574.—A transverse section through the arm, 2 cm. proximal to the med epicondyle of the humerus.

The *medial head* arises from the posterior surface of the body of the hum below the sulcus for the radial nerve; it is narrow and pointed above extends from the insertion of the Teres major to within 2·5 cm. of the tro humeri; it also arises from the medial border of the bone and from the of the whole length of the medial intermuscular septum. Some of the are directed downwards to the olecranon, while others converge to the te of insertion.

The tendon of insertion of the Triceps brachii begins about the mid the muscle. It consists of two aponeurotic laminæ, one of which cover back of the lower one-half of the muscle; the other is more deeply sea the substance of the muscle. After receiving the attachment of the mus fibres, the two lamellæ join together above the elbow, and are inserted, fo most part, into the posterior portion of the upper surface of the olecra a band of fibres is, however, continued downwards, on the lateral side the Anconæus, to blend with the antibrachial fascia.

The long head of the Triceps brachii descends between the Teres minor Teres major, dividing the triangular space between these two muscles and humerus into two smaller spaces, one triangular, the other quadrangular (fig. The triangular space contains the scapular circumflex vessels; it is bounded the Teres minor above, the Teres major below, and the scapular head of the Tr

lly. The quadrangular space transmits the posterior humeral circumflex
s and the axillary nerve; it is bounded by the Subscapularis, the Teres minor
the capsule of the shoulder-joint above, the Teres major below, the long head
Triceps brachii medially, and the humerus laterally.

e Subanconæus is the name given to a few fibres which spring from the deep sur-
of the lower part of the Triceps brachii, and are inserted into the posterior part of
ticular capsule of the elbow-joint.

erves.—The Triceps brachii is supplied by the sixth, seventh and eighth cervical
s through the radial nerve.*

ctions.—The Triceps brachii is the great extensor muscle of the forearm.
n the arm is extended, the long head of the muscle may assist in drawing the
ers backwards and in adducting it to the thorax. The long head supports
ulder part of the shoulder-joint. The Subanconæus draws up the posterior part
e articular capsule of the elbow-joint during extension of the forearm.

pplied Anatomy.—The insertion of the Triceps brachii into the deep fascia of the
ers is of importance in the operation of excision of the elbow, and should always
ssibly preserved. By means of it the patient is enabled to extend the forearm, a
ment which would otherwise be accomplished mainly by gravity—that is to say, by
g the forearm to drop by its own weight.

V. The Muscles of the Forearm

The **antibrachial fascia** (deep fascia of the forearm), continuous above
the brachial fascia, is a dense investment, which forms a general sheath
the muscles in this region; it is attached, behind, to the olecranon and
l border of the ulna, and sends off from its deep surface numerous inter-
ular septa. It gives origin to muscular fibres, especially at the upper part
e medial and lateral sides of the forearm, and forms the boundaries of a
s of cone-shaped cavities, in which the muscles are contained; transverse
s are given off both on the volar and dorsal surfaces of the forearm,
ating the deep from the superficial layers of muscles. It is much thicker
e dorsal than on the volar surface, and at the lower than at the upper
of the forearm, and is strengthened above by tendinous fibres derived
the Biceps brachii in front, and from the Triceps brachii behind. Over
lexor tendons as they approach the wrist it is especially thickened, and
s the volar carpal ligament. This is continuous with the transverse
l ligament, and forms a sheath for the tendon of the Palmaris longus
h passes over the transverse carpal ligament to be inserted into the palmar
onrosis. Behind, near the wrist-joint, it is thickened by the addition
any transverse fibres, and forms the dorsal carpal ligament. Apertures
in the fascia for the passage of vessels and nerves; one of these apertures,
rge size and situated at the front of the elbow, transmits a communicating
h between the superficial and deep veins.

e antibrachial or forearm muscles consist of a volar and a dorsal group.

1. The Volar Antibrachial Muscles

ese muscles are divided for convenience of description into two groups,
cial and deep.

brachial fascia near the elbow, and from the septa which pass from the between the individual muscles.

The **Pronator teres** (figs. 575, 576) has a humeral and an ulnar origin. The *humeral head*, the larger and more superficial, arises in above the medial epicondyle, and tendon common to the origin of muscles; also from the intermuscular between it and the Flexor carpi radi from the antibrachial fascia. The *ulnar head* arises from the medial side coronoid process of the ulna, and humeral head at an acute angle. The nerve enters the forearm between the of the muscle, and is separated from artery by the ulnar head. The muscle obliquely across the forearm, and ends tendon, which is inserted into a rough sion at the middle of the lateral surface body of the radius. The lateral border muscle forms the medial boundary of a hollow, which is situated in front of the joint and contains the median nerve, artery, and tendon of the Biceps brach

Fig. 575.—The left volar antibrachial muscles. Superficial group.

Nerve-supply.—The Pronator teres is by the sixth cervical nerve through the nerve.

Actions.—The Pronator teres rotates radius upon the ulna, turning the palm hand backwards; it also flexes the elbow.

Applied Anatomy.—This muscle, when brought into active use, as in the game of tennis, is apt to be strained, producing slight tenderness, and pain on putting the muscle action. This is known as 'lawn-tennis arm.'

The **Flexor carpi radialis** (figs. 575, 579) lies on the medial side of the Pronator teres. It arises from the medial epicondyle by the common tendon, from the antibrachial fascia, and from the intermuscular between it and the adjacent muscles. Small and aponeurotic in structure at its commencement, it increases in size, and ends in a tendon which passes through a canal in lateral part of the transverse carpal ligament and through a groove on the greater angular bone; the groove is converted canal by fibrous tissue and lined by a sheath. The tendon is inserted into the of the second metacarpal bone, and slip to the base of the third metacarpal In the lower part of the forearm the artery lies between the tendon of this and that of the Brachioradialis.

Nerve-supply.—The Flexor carpi radialis is supplied by the sixth cervical through the median nerve.

Action.—The Flexor carpi radialis flexes the wrist.

The **Palmaris longus** (figs. 575, 576, 587) is a slender, muscle, lying on the medial side of the Flexor carpi radialis. It arises the medial epicondyle of the humerus by the common tendon, from the muscular septa between it and the adjacent muscles, and from the antibrachial fascia. It ends in a long slender tendon which passes over the upper the transverse carpal ligament and is inserted into the anterior surface

between it and the preceding muscles, and from the medial side of the process, above the ulnar origin of the Pronator teres. The radial head, sheet of muscle, arises from the oblique line of the radius, extending radial tuberosity to the insertion of the Pronator teres. The muscle separates into two planes of muscular fibres, superficial and deep; the plane divides into two parts which end in tendons for the middle fingers; the deep plane gives off a muscular slip to join that part of ficial plane which is associated with the tendon of the ring finger divides into two parts, which end in tendons for the index and little As the four tendons pass beneath the transverse carpal ligament palm of the hand, they are arranged in pairs, the superficial pair the middle and ring fingers, the deep pair to the index and little fingers tendons diverge from one another in the palm and form deep relations superficial volar arch and digital branches of the median and ulnar Opposite the bases of the first phalanges each tendon divides into to allow of the passage of the corresponding tendon of the Flexor profundus; the two slips then reunite, partially decussate, and form channel for the reception of the tendon of the Flexor digitorum Finally the tendon divides and is inserted into the sides of the second about its middle.

Nerve-supply.—The Flexor digitorum sublimis is supplied by the eighth cervical and first thoracic nerves through the median nerve.

Actions.—The Flexor digitorum sublimis flexes first the middle and proximal phalanges. It also acts as a flexor of the wrist.

(*b*) *Deep Group* (fig. 577)

Flexor digitorum profundus. Flexor pollicis longus.
Pronator quadratus.

The **Flexor digitorum profundus** (figs. 576, 577, 579) is situated ulnar side of the forearm, deep to the superficial flexors. It arises from upper three-fourths of the volar and medial surfaces of the body of the embracing the insertion of the Brachialis above, and extending to within distance of the Pronator quadratus below. It also arises from a deep on the medial side of the coronoid process of the ulna, and from the upper fourths of the dorsal border of the bone by an aponeurosis, in common the Flexor and Extensor carpi ulnaris; it also springs from the ulnar half interosseous membrane. The muscle ends in four tendons which run the transverse carpal ligament, dorsal to the tendons of the Flexor digitorum sublimis. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the middle, ring, and little fingers are nected together by areolar tissue and tendinous slips, as far as the palm hand. Opposite the first phalanges the tendons pass through the openings the tendons of the Flexor digitorum sublimis, and are inserted into the of the last phalanges.

Nerve-supply.—The Flexor digitorum profundus is supplied by the cervical and first thoracic nerves through the ulnar nerve and the volar interosseous branch of the median nerve.

Actions.—The Flexor digitorum profundus flexes the terminal phalanges the Flexor digitorum sublimis has bent the middle phalanges; it also assists flexing the wrist.

Four small muscles, the Lumbricales, are connected with the tendons the Flexor digitorum profundus in the palm. They will be described with muscles of the hand (p. 526).

Fibrous sheaths of the flexor tendons.—After leaving the the tendons of the Flexores digitorum sublimis et profundus lie in aponeurotic canals (fig. 589, p. 525), formed behind by the phalanges, front by fibrous bands which arch across the tendons, and are attached either side to the margins of the phalanges and to the volar accessory ligaments of the interphalangeal joints. Opposite the middle of the proximal and phalanges the bands (*digital vaginal ligaments*) are very strong, and the are transverse; but opposite the joints they are much thinner, and

annular and *cruciate* fibres. ch canal is lined by a mucous ath, which is reflected on the ained tendons.

s the flexor tendons approach r insertions they are con- ed to the dorsal parts of the losing sheaths by triangular l thread-like bands of the ous sheaths. These bands, ed *vincula tendinum* (fig. 578), very minute vessels to the dons, and are of two kinds, vincula brevia and (*b*) vincula

The *vincula brevia*, two in ber in each finger, are tri- ular bands attached to the deep ces of the tendons close to insertions; one connects the n of the Flexor digitorum nis to the front of the first rphalangeal joint and adjacent of the first phalanx, and the the tendon of the Flexor orum profundus to the front the second interphalangeal joint adjacent part of the second nx. The *vincula longa* are d-like slips, of which two are ly attached to each tendon of Flexor digitorum sublimis, and to each tendon of the Flexor orum profundus. Those of Flexor digitorum sublimis are ed to the slips of that n where these fold over the n of the Flexor digitorum ndus, and, passing one on side of the latter tendon, ached to the sheath at the l margins of the proximal of the first phalanx. That of ndon of the Flexor digitorum ndus is fixed to its tendon y after the latter has pierced ndon of the Flexor digitorum . It runs upwards and rds, perforates one of the ps of the latter tendon, or between the two slips; er it blends with the vin- breve of the Flexor digi- sublimis, and is attached sheath at the distal end of phalanx.

The **Flexor pollicis longus** 577, 579) is situated on the side of the forearm in the plane as the Flexor digi- profundus. It arises from oved volar surface of the of the radius, extending

Fig. 577.—The left volar antibrachial muscles. Deep group.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

from immediately below the tuberosity and oblique line, to within a distance of the Pronator quadratus. It arises also from the adjacent part of interosseous membrane, and generally by a fusiform fleshy slip from the border of the coronoid process below the Flexor digitorum sublimis and p teres, or from the medial epicondyle of the humerus. The fibres e flattened tendon, which passes behind the transverse carpal ligament lodged between the lateral head of the Flexor pollicis brevis and the part of the Adductor pollicis, and, entering an osseo-aponeurotic canal to those for the flexor tendons of the fingers, is inserted into the ba

FIG. 578.—The tendons and the vincula tendinum of the right forefinger. Lateral aspect.

distal phalanx of the thumb. The volar interosseous nerve and vessels on the front of the interosseous membrane between the Flexor pollicis and Flexor digitorum profundus.

Nerve-supply.—The Flexor pollicis longus is supplied by the eighth and first thoracic nerves through the volar interosseous branch of the nerve.

Actions.—The Flexor pollicis longus is a flexor of the phalanges of the it also acts as a flexor of the wrist.

The **Pronator quadratus** (figs. 577, 583) is a flat, quadrilateral extending across the front of the lower parts of the radius and ulna. It from the pronator ridge on the lower part of the volar surface of the the ulna; from the medial part of the volar surface of the lower one of the ulna; and from a strong aponeurosis which covers the medial of the muscle. The fibres pass lateralwards and slightly downwards inserted into the lower one-fourth of the lateral border and the volar of the body of the radius; the deeper fibres are inserted into the area above the ulnar notch of the radius.

Nerve-supply.—The Pronator quadratus is supplied by the eighth first thoracic nerves through the volar interosseous branch of the median

Action.—The Pronator quadratus pronates the forearm, i.e. turns it so palm of the hand is directed backwards.

2. The Dorsal Antibrachial Muscles

These muscles are divided for convenience of description into two groups, superficial and deep.

(a) *Superficial Group* (fig. 580)

Brachioradialis.
Extensor carpi radialis longus.
Extensor carpi radialis brevis.
Anconæus.
Extensor digitorum communis.
Extensor digiti quinti proprius.
Extensor carpi ulnaris.

The **Brachioradialis** (Supinator longus) (figs. 575, 576, 580) is the most superficial muscle on the radial side of the forearm. It arises from the upper two-thirds of the lateral supracondylar ridge of the humerus, and from the

Fig. 579.—A transverse section through the middle of the forearm.

intermuscular septum. Interposed between it and the Brachialis are the nerve and the anastomosis between the arteria profunda brachii and radial recurrent artery. The fibres end above the middle of the forearm in a tendon which is inserted into the lateral side of the base of the styloid process of the radius. The tendon is crossed at its insertion by the tendons of the Abductor pollicis longus and Extensor pollicis brevis; on its ulnar side is the radial artery.

Nerve-supply.—The Brachioradialis is supplied by the fifth and sixth cervical nerves through the radial nerve.

Action.—The Brachioradialis is a flexor of the elbow-joint, but is supplied by a nerve of the extensor muscles, i.e. the radial nerve.

The **Extensor carpi radialis longus** (figs. 576, 580) is partly covered by the Brachioradialis. It arises mainly from the lower one-third of the lateral supracondylar ridge of the humerus and from the lateral intermuscular septum, but it receives a few fibres from the common tendon of origin of the extensor muscles of the forearm. The muscle ends at the upper one-third of the forearm in a flat tendon, which runs along the lateral border of the radius, passes to the Abductor pollicis longus and Extensor pollicis brevis; it then passes under cover of the dorsal carpal ligament, where it lies on the back of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the radius in a groove immediately behind the styloid process. It is
into the radial side of the dorsal surface of the base of the second me
bone.

Nerve-supply.—The Extensor carpi radialis longus is supplied by the
seventh cervical nerves through the deep radial nerve.

Actions.—The Extensor carpi radialis longus extends the wrist and
abducts the hand.

The **Extensor carpi radialis brevis** (figs. 576, 579, 580) is sho
the preceding muscle and is covered by it. It arises from the lateral
of the humerus, by a tendon common to it and the next three muscle
the radial collateral ligament of the elbow-joint; from a strong apo
which covers its surface; and from the intermuscular septa betwee
the adjacent muscles. The fibres end about the middle of the fore
flat tendon, which closely accompanies that of the preceding muscle
wrist; it passes beneath the Abductor pollicis longus and Extensor
brevis, then under cover of the dorsal carpal ligament, and is
into the dorsal surface of the base of the third metacarpal bone on its
side and distal to the styloid process. Under the dorsal carpal ligam
tendon lies on the back of the radius in a shallow groove, on the ulna
of that which lodges the tendon of the Extensor carpi radialis long
separated from it by a faint ridge.

The tendons of the two preceding muscles pass through the same co
ment of the dorsal carpal ligament in a single mucous sheath.

Nerve-supply.—The Extensor carpi radialis brevis is supplied by the
seventh cervical nerves through the radial nerve.

Action.—The Extensor carpi radialis brevis extends the wrist.

The **Extensor digitorum communis** (figs. 576, 579, 580) arises fr
lateral epicondyle of the humerus, by the common tendon; from the
muscular septa between it and the adjacent muscles, and from the anti
fascia. It divides below into four tendons, which pass, together wi
of the Extensor indicis proprius, through a compartment of the dorsal
ligament, within a mucous sheath. The tendons then diverge on the
of the hand, and are inserted into the second and third phalanges of the
in the following manner. Opposite the metacarpophalangeal arti
each tendon is bound by fasciculi to the collateral ligaments and se
the dorsal ligament of this joint; after crossing the joint, it spreads
broad aponeurosis, which covers the dorsal surface of the first phala
is there reinforced by the corresponding tendons of the Interosse
Lumbricalis. Opposite the first interphalangeal joint this aponeurosis
into three slips, an intermediate and two collateral: the interme
inserted into the base of the second phalanx; the two collateral are co
onwards along the sides of the second phalanx, and uniting by their co
margins, are inserted into the dorsal surface of the ungual phalanx.
tendons cross the interphalangeal joints, they serve as dorsal ligaments
tendon to the index finger is accompanied by the Extensor indicis pr
which lies on its ulnar side. On the back of the hand, the tendons
middle, ring, and little fingers are connected by two obliquely placed
one from the third tendon passing distalwards and lateralwards
second tendon, and the other passing from the fourth tendon to the
Occasionally the second tendon is connected to the first by a thin
band.

Nerve-supply.—The Extensor digitorum communis is supplied by the
cervical nerve through the deep radial nerve.

Actions.—The Extensor digitorum communis extends the phalanges
the wrist. Owing to its attachments to the collateral ligaments of the meta
phalangeal joints it acts principally on the proximal phalanges, the midd
terminal phalanges being extended mainly by the Interossei and Lumbrica
tends to separate the fingers as it extends them.

The **Extensor digiti quinti proprius** (fig. 580) is a slender muscle
to, and usually connected with, the Extensor digitorum communis. It
from the common extensor tendon by a thin tendinous slip, and fro
intermuscular septa between it and the adjacent muscles. Its tendon
through a compartment of the dorsal carpal ligament behind the

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Extensor indicis proprius** (fig. 581) is a narrow, elongated medial to, and parallel with, the preceding. It arises from the dorsal of the body of the ulna below the origin of the Extensor pollicis longus from the interosseous membrane. Its tendon passes under cover of the carpal ligament in the compartment which transmits the tendons of Extensor digitorum communis; opposite the head of the second metacarpal bone it joins the ulnar side of the tendon of the Extensor digitorum communis which runs to the index finger.

Nerve-supply.—The Extensor indicis proprius is supplied by the seventh nerve through the deep radial nerve.

Actions.—The Extensor indicis proprius extends the index finger, and also extending the wrist.

Applied Anatomy.—The tendons of the Abductor longus and extensors of the are liable to become strained, and their sheaths inflamed (*tenosynovitis*) after exercise, producing a sausage-shaped swelling along the course of the tendons and a peculiar grating sensation to the touch when the muscles are put in action.

Paralysis of the extensor muscles of the wrists and fingers resulting in 'wrist is common in lead poisoning in painters. The different extensor muscles are unequally as a rule. Thus the thumb, or index, or little finger may be but slightly cated, and recover rapidly while the extensors of the other fingers or wrist remain less; and some of the flexor muscles of the fingers may become paretic. This selective action of the lead in cases of lead poisoning depends in reality upon over use of the affected muscles or groups of muscles.

VI. The Muscles of the Hand

The muscles of the hand are subdivided into three groups: 1, those thumb, which occupy the radial side and produce the *thenar* eminence; 2, those of the little finger, which occupy the ulnar side and give rise *hypothenar* eminence; 3, those in the middle of the palm and between metacarpal bones.

Fig. 583.—A transverse section through the distal ends of the left radius and ulna. Superior aspect.

The **volar carpal ligament** is the thickened band of antibrachial which extends from the radius to the ulna in front of the flexor tendons they approach the wrist.

The **transverse carpal ligament** (anterior annular ligament) (figs. 584, is a strong, fibrous band, which crosses the front of the carpus, and converts the concavity formed by the volar surfaces of the carpal bones into a through which the flexor tendons of the digits and the median nerve It is attached, medially, to the pisiform bone and to the hamulus of the hamate bone; laterally, it splits into two laminæ, a superficial attached to the tubercle

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the navicular and greater multangular bones, and a deep to the posterior lip the groove on the latter bone; the two laminæ form with the groove on the greater multangular bone a tunnel which is traversed by a mucous sheath containing the tendon of the Flexor carpi radialis. The ligament is continuous, above, with the volar carpal ligament; and below, with the palmar aponeurosis. It is crossed superficially by the ulnar vessels and nerve, and the cutaneous branches of the median and ulnar nerves. On its volar surface the tendons of the Palmaris longus and Flexor carpi ulnaris are partly inserted; below, it gives origin to the short muscles of the thumb and little finger.

The mucous sheaths of the tendons on the front of the wrist.—Two mucous sheaths envelop the flexor tendons as they traverse the carpal tunnel, one for the Flexores digitorum sublimis et profundus, the other for the Flexor pollicis longus (fig. 585). These sheaths extend into the forearm for about 4 cm. above the transverse carpal ligament, and occasionally communicate with each other behind the ligament. The sheath of the Flexores digitorum

Fig. 584.—A transverse section through the left wrist. Superior aspect.

ulum reaches about halfway along the metacarpal bones, where it ends in and diverticula around the tendons to the index, middle, and ring fingers. is prolonged on the tendons to the little finger and usually communicates with the digital mucous sheath of these tendons. The sheath of the tendon the Flexor pollicis longus is continued along the thumb as far as the insertion the tendon. The mucous sheaths enveloping the terminal parts of the tendons of the Flexores digitorum have been described (p. 510).

The **dorsal carpal ligament** (posterior annular ligament) (fig. 586) is a long, fibrous band, extending obliquely across the back of the wrist, and consisting of part of the antibrachial fascia, strengthened by the addition of some transverse fibres. It is attached, medially, to the styloid process of the ulna and to the triquetral and pisiform bones; laterally, to the lateral margin of the radius; and, in its passage across the wrist, to the ridges on the dorsal surface of the radius.

The mucous sheaths of the tendons on the back of the wrist.—Beneath the dorsal carpal ligament there are six compartments for the passage of the extensor tendons, each compartment containing a mucous sheath. This is found in each of the following positions (fig. 586): (1) on the lateral side of the styloid process, for the tendons of the Abductor pollicis longus and Extensor pollicis brevis; (2) behind the styloid process, for the tendons of the Extensores carpi radiales longus et brevis; (3) about the middle of the dorsal surface of the radius, for the tendon of the Extensor pollicis longus; (4) to the medial side of the latter, for the tendons of the Extensor digitorum

slip subdivides into two processes, which are inserted into the fibrous
of the flexor tendons; from the sides of these processes offsets are
to the transverse metacarpal ligament. By this arrangement short
are formed on the front of the heads of the metacarpal bones; through
the flexor tendons pass. The intervals between the four slips trans
digital vessels and nerves, and the tendons of the Lumbricales. At the
of division into the slips mentioned, numerous strong, transverse fib

Fig. 587.—The right palmar aponeurosis.

the separate processes together. The central part of the palmar aponeu
is intimately bound to the skin by dense fibro-areolar tissue, and gives
by its medial margin to the Palmaris brevis. It covers the superficial
arch, the tendons of the Flexores digitorum, the terminal part of the m
nerve, and the superficial part of the ulnar nerve; on either side it give
a septum which separates the intermediate from the lateral and medial
of muscles.

The *lateral and medial portions* of the palmar aponeurosis are thin, fi
layers, which cover the muscles of the ball of the thumb, and the short m
of the little finger respectively; they are continuous with the central p
and with the fascia on the dorsum of the hand.

The **superficial transverse fasciculi** form a thin band (fig. 587)
stretches across the roots of the fingers, and is attached to the skin

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

...s, and medially to the fifth metacarpal bone, forming a sort of rudimentary ... The digital vessels and nerves pass beneath these fasciculi.

...*plied Anatomy.*—The palmar aponeurosis is liable to undergo contraction, pro-... a very inconvenient deformity known as 'Dupuytren's contraction.' The ring ... little fingers are most frequently implicated, but the others may also be involved. ... proximal phalanx is flexed and cannot be straightened, and the two distal phalanges ... are similarly flexed as the disease advances.

Owing to their constant exposure to injury and septic influences, the fingers are very ... to become the seat of serious inflammatory mischief. In some cases, the inflam-... may involve the theca of the flexor tendons, and a *thecal paronychia* may result. ... inflammation then rapidly spreads up the sheath; but the extent will depend upon ... particular digit involved. From the description of the flexor sheaths given above, it ... evident that inflammation of the mucous sheaths of the thumb and little finger ... prove a far more formidable affection than that of the other three digits, because the ... of these two digits communicate with the large mucous sheath which surrounds ... flexor tendons (p. 519), and the inflammation may extend into the palm of the hand ... behind the transverse carpal ligament into the forearm.

In order to relieve these conditions, free and early incisions are necessary, and must be ... with discrimination, in order to avoid wounding important structures. In the pulp ... finger—i.e. over the distal phalanx—the incision should be made in the middle line ... down to the bone. In the rest of the finger, the incision should be made in the middle ... over the phalanges, and not over the interphalangeal joints. In the palm of the hand, ... may be made either on the distal or proximal side of the superficial volar arch. ... distal side the incisions should be made over the metacarpal bones, preferably ... of the index and middle finger. On the proximal side, the safest line of incision is ... the radial side of the hypothenar eminence, between the ulnar artery and nerve ... and the median nerve laterally. When suppuration has extended under the ... transverse carpal ligament, and incisions are required in the forearm, the positions in ... they should be made are over the tendons of the Flexor digitorum sublimis, ... the median nerve and the ulnar artery, and over the tendon of the Flexor pollicis ... between the radial artery and the tendon of the Flexor carpi radialis.

Chronic inflammation of the common flexor sheath is occasionally met with, consti-... a disease known as *compound palmar ganglion*; it presents an hour-glass outline, ... a swelling in front of the wrist and another in the palm of the hand, and a constric-... corresponding to the transverse carpal ligament, between the two. The fluid can ... from the one swelling to the other under the ligament, and when this is done, a ... sensation is sometimes perceived, from the presence of 'melon-seed' bodies in ... interior of the ganglion.

1. The Lateral Volar Muscles (figs. 588, 589)

Abductor pollicis brevis.	Flexor pollicis brevis.
Opponens pollicis.	Adductor pollicis.

The **Abductor pollicis brevis** (fig. 589) is a thin, subcutaneous muscle; ... arises from the transverse carpal ligament, the tuberosity of the navicular ... and the ridge of the greater multangular bone. It is inserted by a thin, ... tendon into the radial side of the base of the first phalanx of the thumb ... the capsule of the metacarpophalangeal articulation.

Nerve-supply.—The Abductor pollicis brevis is supplied by the sixth and seventh ... nerves through the median nerve.

Actions.—The Abductor pollicis brevis draws the thumb forwards in a plane ... angles to the palm of the hand and abducts the proximal phalanx.

The **Opponens pollicis** (figs. 588, 589) is placed beneath the Abductor ... brevis. It arises from the ridge on the greater multangular bone, and ... the transverse carpal ligament, and is inserted into the whole of the ... lateral surface of the metacarpal bone of the thumb on its radial side.

Nerve-supply.—The Opponens pollicis is supplied by the sixth and seventh ... nerves through the median nerve.

Actions.—The Opponens pollicis flexes the metacarpal bone of the thumb, i.e. ... it medialwards across the palm of the hand.

The **Flexor pollicis brevis** (fig. 589) consists of two portions, superficial ... deep. The *superficial portion* arises from the lower border of the transverse ... ligament and the lower part of the ridge on the greater multangular

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

bone ; it passes along the radial side of the tendon of the Flexor pollicis l and is inserted into the radial side of the base of the first phalanx of the th in its tendon of insertion there is a sesamoid bone. The *deep portion* small. It arises from the ulnar side of the base of the first metacarpal and is inserted into the ulnar side of the base of the first phalanx oblique part of the Adductor pollicis ; it is sometimes described as *volar interosseous* muscle.

Nerve-supply.—The superficial portion of the Flexor pollicis brevis is by the sixth and seventh cervical nerves through the median nerve ; the deep by the eighth cervical nerve through the ulnar nerve.

Actions.—The Flexor pollicis brevis flexes and adducts the proximal ph the thumb.

FIG. 588.—The right Opponens pollicis, Adductor pollicis and Opponens digiti q

The **Adductor pollicis** (fig. 588) consists of an oblique and a trans part. The *oblique part* arises from the capitate and lesser multangular bo the bases of the second and third metacarpal bones, the intercarpal ligam and the sheath of the tendon of the Flexor carpi radialis. Most of its converge to a tendon, which, uniting with the tendons of the deep portio the Flexor pollicis brevis and the transverse part of the Adductor, is inser into the ulnar side of the base of the first phalanx of the thumb, a sesam bone being present in the tendon. A considerable fasciculus, however, p beneath the tendon of the Flexor pollicis longus and joins the superficial po of the Flexor pollicis brevis and the Abductor pollicis brevis. The *trans part* (fig. 588) is the most deeply seated of this group of muscles. It is triangular form, and arises from the distal two-thirds of the volar surfa the third metacarpal bone ; the fibres converge, to be inserted with the obl part of the muscle and with the deep part of the Flexor pollicis brevis the ulnar side of the base of the first phalanx of the thumb.

Nerve-supply.—The Adductor pollicis is supplied by the eighth cervical n through the ulnar nerve.

Action.—The Adductor pollicis approximates the thumb to the palm of hand.

2. The Medial Volar Muscles (figs. 588, 589)

Palmaris brevis.
Abductor digiti quinti.
Flexor digiti quinti brevis.
Opponens digiti quinti.

The **Palmaris brevis** (fig. 587) is a thin, quadrilateral muscle, placed beneath the skin of the ulnar side of the hand. It arises by tendinous fasciculi

Fig. 589.—The muscles of the left hand. Volar aspect.

the transverse carpal ligament and palmar aponeurosis; the fleshy fibres inserted into the skin on the proximal part of the ulnar border of the hand. **Nerve-supply.**—The Palmaris brevis is supplied by the eighth cervical nerve through the ulnar nerve.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Action.—The Palmaris brevis corrugates the skin on the ulnar side of the hand.

The **Abductor digiti quinti** (fig. 589) is situated on the ulnar side of the palm of the hand. It arises from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and ends in a flat tendon which divides into two; one is inserted into the ulnar side of the base of the first phalanx of the little finger, the other into the ulnar border of the aponeurosis of the Extensor digiti quinti proprius.

Nerve-supply.—The Abductor digiti quinti is supplied by the eighth cervical nerve through the ulnar nerve.

Action.—The Abductor digiti quinti abducts the proximal phalanx of the little finger.

The **Flexor digiti quinti brevis** (fig. 589) lies on the radial side of the preceding muscle. It arises from the convex surface of the hamulus of the hamate bone and the volar surface of the transverse carpal ligament; it is inserted into the ulnar side of the base of the first phalanx of the little finger. It is separated from the Abductor by the deep volar branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is usually, of large size.

Nerve-supply.—The Flexor digiti quinti brevis is supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The Flexor digiti quinti brevis flexes and abducts the proximal phalanx of the little finger.

The **Opponens digiti quinti** (fig. 588) is of a triangular form, and lies under cover of the Flexor and Abductor. It arises from the convex surface of the hamulus of the hamate bone, and contiguous portion of the transverse carpal ligament; it is inserted into the whole length of the ulnar margin of the fifth metacarpal bone.

Nerve-supply.—The Opponens digiti quinti is supplied by the eighth cervical nerve through the ulnar nerve.

Action.—The Opponens digiti quinti draws forwards the fifth metacarpal so as to deepen the hollow of the palm.

3. The Intermediate Muscles

Lumbricales. Interossei.

The **Lumbricales** (fig. 589) are four small fleshy fasciculi, which take origin from the tendons of the Flexor digitorum profundus. The first and second arise from the radial sides and volar surfaces of the tendons of the index and middle fingers respectively; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and opposite the metacarpophalangeal articulation is inserted into the tendinous expansion of the Extensor digitorum communis covering the dorsal surface of the finger.

Nerve-supply.—The first and second Lumbricales are supplied by the eighth and seventh cervical nerves through the median nerve; the third and fourth Lumbricales by the eighth cervical through the ulnar nerve. The third Lumbricalis frequently receives a twig from the median nerve.

Actions.—The Lumbricales flex the proximal and extend the middle and terminal phalanges.

The **Interossei** occupy the intervals between the metacarpal bones, and are divided into a dorsal and a volar set.

The **Interossei dorsales** (fig. 590), four in number, are bipennate muscles, each arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeuroses of the tendons of the Extensor digitorum communis. Between the double origin of each of these muscles is a narrow triangular interval; through the first of these intervals the radial artery passes; through each of the others a perforating branch from the deep volar arch is transmitted. The *first* or *Abductor indicis* is larger than the others; it is inserted into

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

dial side of the index finger. The *second* and *third* are inserted into the dle finger, the former into its radial, the latter into its ulnar side. The rth is inserted into the ulnar side of the ring finger.

The **Interossei volares** (fig. 591), three in number, are smaller than the rossei dorsales, and are placed upon the volar surfaces of the metacarpal es, rather than between them. Each arises from the entire length of the tacarpal bone of one finger, and is inserted into the side of the base of the first alanx of the same finger, and into the aponeurosis of the Extensor digitorum communis tendon.

Fig. 590.—The Interossei dorsales of the left hand. Dorsal aspect.

Fig. 591.—The Interossei volares of the left hand. Volar aspect.

The *first* arises from the ulnar side of the second metacarpal bone, and is rted into the same side of the first phalanx of the index finger. The *second* s from the radial side of the fourth metacarpal bone, and is inserted into ame side of the ring finger. The *third* arises from the radial side of the metacarpal bone, and is inserted into the same side of the little finger. n this account it may be seen that each finger is provided with a pair of rossei, with the exception of the little finger, in which the Abductor digiti ti takes the place of one of the pair.

s already mentioned (p. 524), the deep head of Flexor pollicis brevis is times described as the first volar interosseous muscle.

Nerve-supply.—The Interossei dorsales et volares are supplied by the eighth al nerve through the ulnar nerve.

Actions.—The Interossei dorsales abduct the fingers from an imaginary line n longitudinally through the centre of the middle finger; and the Interossei s adduct the fingers to that line. The Interossei, in conjunction with the bricales, flex the first phalanges, and, in consequence of their insertions into xpansions of the Extensor tendons, extend the second and third phalanges.

pplied Anatomy.—In considering the actions of the various muscles upon fractures e upper extremity, the most common forms of injury have been selected both for ation and description.

fracture of the *middle of the clavicle* (fig. 592) is usually attended with considerable acement of the lateral fragment, which is drawn downwards and medialwards, and e same time rotated, so that its lateral end is carried forwards and its medial end wards.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The displacement is produced as follows: the lateral fragment is drawn down by the weight of the arm, the Trapezius not being able to support this. It is drawn forwards by the Subclavius and Pectoralis minor, possibly assisted by the Pectoralis major and Latissimus dorsi; and is rotated on an axis drawn through its own centre. Serratus anterior, which causes the scapula to rotate on the wall of the chest, and the acromion and the end of the lateral fragment of the clavicle forwards, and the medial end of the lateral portion backwards. Lying on the back keeps the parts in position and allows gravity to rectify the displacement of the lateral fragment.

In fracture of the *acromial end of the clavicle*, between the conoid and the ligaments, only slight displacement occurs, as these ligaments, from their obliquity, serve to hold both portions of the bone in apposition. Fracture, also, of the *end*, medial to the costoclavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fig. 592.—A fracture of the middle of the clavicle.

Fig. 593.—A fracture of the surgical neck of the humerus.

Fracture of the *acromion* is usually caused by violence applied to the upper and back part of the shoulder. There is great displacement; the lateral fragment being drawn downwards by the weight of the arm, and rotated forwards and medialwards, so that it forms a right angle with the rest of the bone.

Fracture of the *surgical neck of the humerus* (fig. 593) is very common. It is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment remains in its place under the coraco-acromial ligament; the lower is drawn medialwards by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrust obliquely from the side of the chest by the Deltoideus, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process.

In fracture of the *body of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoideus, there is considerable deformity, the upper fragment being drawn medialwards by the above mentioned muscles, and the lower fragment upwards and lateralwards by the Deltoideus. Shortening of the limb results, with a considerable prominence at the seat of fracture from the fractured ends of the bone riding over one another, especially if the fracture take place in an oblique direction.

In fracture of the *body of the humerus* immediately below the insertion of the Deltoideus the amount of deformity depends greatly upon the direction of the fracture. If it occur in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forwards; but in oblique fracture, the combined action of the Biceps brachii and Brachialis in front and the Triceps brachii behind draw up the lower fragment, causing it to glide over the upper, either backwards or forwards

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ording to the direction of the fracture. It is in this fracture that the chest-wall is found make the best splint for the medial side of the bone.

Fracture of the *humerus* immediately above the condyles (fig. 594) deserves very attentive deration, as the general appearances correspond somewhat with those produced by ation of the epiphysis of the humerus, and with those of dislocation of the radius and backwards. If the direction of the fracture is oblique, from above, downwards and

Fig. 594.—A fracture of the humerus above the condyles.

Fig. 595.—A fracture of the olecranon.

wards, the lower fragment is drawn upwards by the Brachialis and Biceps brachii in and the Triceps brachii behind; and at the same time is drawn backwards behind upper fragment by the Triceps brachii. This fracture may be diagnosed from dis- ion, by the increased mobility, the existence of crepitus, and the fact that the deformity medied by extension, but is reproduced on the discontinuance of it. The age of the nt is of importance in distinguishing this form of injury from separation of the epiphysis. me cases where the injury has been produced by falls on the elbow, the lower fragment own upwards and forwards, causing a considerable prominence in front, the upper ment projecting backwards beneath the tendon of the Triceps brachii. In the treatment ftures of the lower end of the humerus, acute flexion of the elbow-joint gives the best ts; this is especially so in children.

In fracture of the *olecranon* (fig. 595) the detached fragment is displaced upwards from to 5 cm. by the action of the Triceps brachii; the prominence of the elbow is con- ently lost, and a deep hollow is felt at the back part of the joint, which is much increased ering the limb. The patient at the same time loses, more or less, the power of extending forearm.

In fracture of the *radius* below the insertion of the Biceps brachii, but above the insertion Pronator teres, the upper fragment is strongly supinated by the Biceps brachii and nator, and at the same time drawn ards by the Biceps brachii, the r fragment is pronated and drawn ds the ulna by both Pronators. there is extreme displacement very little deformity. This frac- should be treated with the hand full supination so as to insure that fragment of the radius will be ated to the extent of the upper ment.

Fig. 596.—A fracture of the body of the radius.

In fractures of the radius below the tion of the Pronator teres (fig. 596), upper fragment is drawn upwards the Biceps brachii and medialwards by the Pronator teres, into a position midway en pronation and supination, and a degree of fulness in the upper half of the forearm s produced. The lower fragment is drawn downwards towards the ulna and pronated the Pronator quadratus; at the same time, the Brachioradialis, by elevating the styloid ess, into which it is inserted, will serve to depress the upper end of the lower fragment more towards the ulna.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In fracture of the *body of the ulna* the upper fragment retains its usual position, the lower is drawn towards the radius by the Pronator quadratus, producing a well depression at the seat of fracture, and some fulness on the dorsal and volar surfaces of the forearm.

In fracture of the *bodies of the radius and ulna together*, the lower fragments are drawn upwards, sometimes forwards, sometimes backwards, according to the direction of the fracture, by the combined actions of the flexor and extensor muscles, producing a fulness on either the dorsal or volar surface of the forearm. At the same time the fragments are drawn into contact by the Pronator quadratus, the radius being in the of pronation. The upper fragment of the radius is drawn upwards and medially by the Biceps brachii and Pronator teres to a higher level than the ulna; the upper of the ulna is slightly elevated by the Brachialis.

Fig. 597.—A fracture of the lower end of the radius.

In fracture of the *lower end of the radius* (fig. 597) the displacement produced is considerable, and bears some resemblance to dislocation of the carpus backwards, which it should be carefully distinguished. The lower fragment is displaced backwards and upwards, but this displacement is due to the force of the blow driving the portion of the bone into this position, and not to any muscular influence. The upper fragment projects forwards, often lacerating the substance of the Pronator quadratus, and is held by this muscle into close contact with the lower end of the ulna, causing a projection on the volar surface of the forearm, immediately above the carpus, from the flexor tendons being thrust forwards. This fracture may be distinguished from dislocation by the relative positions of the styloid processes of the radius and ulna (the former of which is displaced upwards in fracture) and by the deformity being removed on making sufficient extension when crepitus may be occasionally detected. The age of the patient will assist in determining whether the injury is fracture or separation of the epiphysis. During treatment of this fracture the wrist should be kept fully hyperextended (p. 395).

THE FASCIÆ AND MUSCLES OF THE LOWER EXTREMITY

The muscles of the lower extremity are subdivided into groups corresponding with the different regions of the limb.

I. Muscles of the iliac region.
II. Muscles of the thigh.
III. Muscles of the leg.
IV. Muscles of the foot.

I. The Muscles of the Iliac Region (fig. 598)

Psoas major. Psoas minor. Iliacus.

The **fascia iliaca** covers the Psoas and Iliacus. It is thin above, but becomes gradually thicker as it approaches the inguinal ligament.

The *portion covering the Psoas* is thickened above to form the medial lumbo-costal arch which stretches from the transverse process of the first to the body of the second lumbar vertebra. Medially, this portion of the fascia is attached by a series of arched processes to the intervertebral fibrocartilages and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum. Laterally, above the crest of the ilium, it is continuous with the fascia covering the front of the Quadratus lumborum (p. 481), while below the crest of the ilium it is continuous with the fascia covering the Iliacus.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The portion covering the Iliacus is con-
cted, laterally, to the whole length of
e inner lip of the iliac crest; and medi-
ly to the brim of the lesser pelvis, where
blends with the periosteum. It is
ached to the iliopectineal eminence,
d there receives a slip from the tendon
insertion of the Psoas minor when that
scle exists. The external iliac vessels
e in front of the fascia but the branches
the lumbar plexus are behind it; it is
parated from the peritoneum by a part
the subperitoneal connective tissue
ascia of Abernethy).

Lateral to the femoral vessels, the iliac
ascia is intimately connected to the pos-
rior margin of the inguinal ligament,
d is continuous with the transversalis
ascia. It passes behind the femoral
essels, and beyond the inguinal ligament
mes the *iliopectineal fascia*. This
n divides the space between the
guinal ligament and the hip-bone into
edial and a lateral lacuna; the medial
cuna vasorum) transmits the femoral
essels, the lateral (lacuna musculorum)
e Psoas major, the Iliacus and the
moral nerve. Medial to the vessels the
pectineal fascia is attached to the pecten
bis, and is continuous with the pectineal
ascia. In the thigh the iliopectineal
ascia covers the Iliacus and the Psoas
jor, and forms the posterior wall of the
moral sheath.

The **Psoas major** (fig. 598) is a long
form muscle placed on the side of the
mbar region of the vertebral column and
e brim of the lesser pelvis. It arises
from the anterior surfaces and lower
rders of the transverse processes of all
e lumbar vertebræ; (2) by five slips or
tations, each of which takes origin from
e bodies of two vertebræ and their inter-
ertebral fibrocartilage; the highest slip
ises from the lower margin of the body
the twelfth thoracic vertebra, the upper
rgin of the body of the first lumbar
rtebra and the interposed fibrocartilage,
e lowest slip from the adjacent margins
the bodies of the fourth and fifth lumbar
rtebræ and the interposed fibrocartilage;
from a series of tendinous arches
anding across the constricted parts of
e bodies of the lumbar vertebræ between
e preceding slips; the lumbar arteries
d veins, and filaments from the sympa-
hic trunk, pass beneath these arches.
e muscle proceeds downwards across
brim of the lesser pelvis, passes behind
inguinal ligament and in front of the
ule of the hip-joint, and ends in a
on. The latter receives nearly the
le of the fibres of the Iliacus and is

FIG. 598.—The muscles of the iliac region and the anterior femoral muscles. Right side.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

inserted into the lesser trochanter of the femur. A large bursa, which communicate with the cavity of the hip-joint, separates the tendon from os pubis and the capsule of the joint.

Relations.—In the abdomen the Psoas major is in relation by its *anterior surface* with the medial lumbocostal arch, the fascia covering the muscle, the extraperitoneal connective tissue and peritoneum, the kidney, Psoas minor, renal vessels, ureter, testicular (or ovarian) vessels, and genito-femoral nerve. In front of the right Psoas is the inferior vena cava, and the terminal portion of the ileum, and in front of the left the colon. Its *posterior surface* is in relation with the transverse processes of the lumbar vertebræ, and the quadratus lumborum. The lumbar plexus is situated in the posterior part of the muscle, and the of the muscle. *Medially*, the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the gangliated trunk of the sympathetic, the lumbar lymph-glands, and along the brim of the pelvis with the external iliac artery; medial to the right is the inferior vena cava, and to the left muscle the aorta.

In the thigh it is in relation, *in front*, with the fascia lata; *behind*, with the capsule of the hip-joint from which it is separated by a bursa; by its *medial border*, with the obturator tineus and medial femoral circumflex artery, and also with the femoral artery, which slightly overlaps it; by its *lateral border*, with the Iliacus.

The femoral nerve descends at first through the fibres of Psoas major, then lies between it and the Iliacus, and at the level of the inguinal ligament is in front of the muscle.

Nerve-supply.—The Psoas major is supplied by branches from the second and third lumbar nerves.

Actions.—The Psoas major acts conjointly with the Iliacus.

The **Psoas minor** (fig. 598) is placed in front of the Psoas major within the abdomen. It arises from the sides of the bodies of the twelfth thoracic and first lumbar vertebræ and from the fibrocartilage between them. It ends in a long flat tendon which is inserted into the pecten pubis and iliopectineal eminence, and, by its lateral border, into the iliac fascia. This muscle is absent in about 40 per cent. of subjects.

Nerve-supply.—The Psoas minor is supplied by a branch from the first lumbar nerve.

Action.—The Psoas minor is a tensor of the iliac fascia.

The **Iliacus** (fig. 598) is a flat, triangular muscle, which fills the iliac fossa. It arises from the upper two-thirds of the iliac fossa, from the inner lip of the iliac crest, from the anterior sacro-iliac and iliolumbar ligaments, and from the ala of the sacrum; in front, it reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the articular capsule of the hip-joint. Most of its fibres converge to be inserted into the lateral side of the tendon of the Psoas major, but some of them are attached to the body of the femur for 2·5 cm. below and in front of the lesser trochanter.*

Relations.—Within the abdomen the Iliacus is in relation by its *anterior surface* with the iliac fascia, which separates the muscle from the extraperitoneal connective tissue and peritoneum, and with the lateral femoral cutaneous nerve; on the right side, with the cæcum; on the left side, with the iliac part of the descending colon; by its *posterior surface* with the iliac fossa; by its *medial border*, with the Psoas major and femoral nerve.

In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus femoris, Sartorius, and arteria profunda femoris; by its *posterior surface*, with the capsule of the hip-joint, a bursa common to it and the Psoas major being interposed.

Nerve-supply.—The Iliacus is supplied by branches of the second and third lumbar nerves, through the femoral nerve.

Actions.—The Psoas major, acting from above, flexes the thigh upon the pelvis, being assisted by the Iliacus; acting from below, with the femur fixed, it bends the lumbar portion of the vertebral column forwards and to its own side, and thereby, in conjunction with the Iliacus, tilts the pelvis forwards. When the Psoas major and Iliacus of both sides act from below, they serve to maintain the erect posture by supporting the vertebral column and pelvis upon the femora, or in continued action bend the trunk and pelvis forwards, as in raising the trunk from the recumbent posture.

Applied Anatomy.—There is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an abscess forms beneath the

* The Psoas major and Iliacus are sometimes regarded as a single muscle named the *Iliopsoas*.

Digitized by Arya Samaj Foundation Chennai and eGangotri

...a, as it is very apt to do, the pus is contained in an osseofibrous cavity which is closed ...all sides within the abdomen, and is open only at its lower part, where the fascia is ...nged over the muscles into the thigh. When the disease is in the thoracic vertebræ, ...matter tracks down the posterior mediastinal cavity in front of the bodies of the ...brræ, and, passing beneath the medial lumbocostal arch, enters the sheath of the ...s, down which it travels as far as the pelvic brim; it then gets beneath the iliac ...ion of the fascia, and fills up the iliac fossa. In consequence of the attachment of ...fascia to the linea terminalis, it rarely finds its way into the lesser pelvis, but passes ...a narrow opening under the inguinal ligament into the thigh, lateral to the femoral ...sels. It thus follows that a psoas abscess may be described as consisting of four parts, ...(1) somewhat narrow channel at its upper part, in the psoas sheath; (2) a dilated sac ...the iliac fossa; (3) a constricted neck under the inguinal ligament; and (4) a dilated ...the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, ...matter finds its way directly into the substance of the Psoas. The muscular fibres ...destroyed, and the nerves contained in the abscess are isolated and exposed in its ...rior; the iliac vessels which lie in front of the fascia remain intact, and the peri-...um seldom becomes implicated. All psoas abscesses do not, however, pursue this ...se; the pus may leave the sheath of the muscle above the crest of the ilium, and ...ing backwards may point in the loin (*lumbar abscess*); or it may point above the ...inal ligament in the inguinal region; or it may follow the course of the branches of ...hypogastric vessels into the lesser pelvis, and, passing through the greater sciatic ...men, discharge itself on the back of the thigh.

II. The Muscles of the Thigh

1. The Anterior Femoral Muscles (fig. 598)

Tensor fasciæ latæ.
Sartorius.
Quadriceps femoris { Rectus femoris. Vastus lateralis. Vastus medialis. Vastus intermedius.
Articularis genus.

The **superficial fascia** forms a continuous layer over the whole of the ...; it consists of areolar tissue containing in its meshes much fat, and ...be separated into two or more layers, between which are found the super-...l vessels and nerves. It varies in thickness in different parts of the limb; ...the groin it is thick, and the two layers are separated from one another ...the superficial inguinal lymph-glands, the great saphenous vein, and several ...er vessels. The superficial layer is continuous above with the super-...l fascia of the abdomen. The deep layer of the superficial fascia is a ...thin, fibrous stratum, best marked on the medial side of the great saphenous ...and below the inguinal ligament. It is placed beneath the subcutaneous ...ls and nerves and upon the surface of the fascia lata. It is intimately ...rent to the fascia lata a little below the inguinal ligament. It covers the ...a ovalis (saphenous opening), being closely united to its circumference, ...is connected to the sheath of the femoral vessels. The portion covering ...fossa ovalis is perforated by the great saphenous vein, small blood-...ls, and lymph-vessels, hence it has been termed the *fascia cribrosa*, the ...ings for these vessels having been likened to the holes in a sieve. A large ...taneous bursa is found in the superficial fascia over the patella.

The **deep fascia** of the thigh is named, from its great extent, the *fascia* ...; it constitutes an investment for the whole of this region of the limb, ...varies in thickness in different parts. Thus, it is thicker in the upper ...lateral parts of the thigh, where it receives a fibrous expansion from the ...us maximus, and where the Tensor fasciæ latæ is inserted between its ...s; it is very thin behind, and at the upper and medial parts, where it covers ...adductor muscles, but becomes stronger around the knee, where it receives ...us expansions from the tendon of the Biceps femoris laterally, from the ...torius medially, and from the Quadriceps femoris in front. The fascia lata ...tached, above and behind, to the back of the sacrum and coccyx; laterally, ...the iliac crest; in front, to the inguinal ligament and to the superior ramus of ...s pubis; and medially, to the inferior ramus of the os pubis, to the inferior ...us and tuberosity of the ischium, and to the lower border of the sacro-...ous ligament. From its attachment to the iliac crest it descends as a ...e fascia over the Glutæus medius to the upper border of the Glutæus

Digitized by Arya Samaj Foundation Chennai and eGangotri
maximus, where it splits into two layers, one passing superficial and the deep to this muscle; at the lower border of the muscle the two layers re The portion of the fascia lata attached to the front part of the iliac crest corresponding to the origin of the Tensor fasciæ latæ, extends down the side of the thigh as two layers, one superficial and the other deep muscle; at the lower end of the muscle these two layers unite, and strong band, having first received the insertion of the muscle. This continued downwards, under the name of the *iliotibial tract* (iliotibial band is attached to the lateral condyle of the tibia. The layer of the iliotibial which lies deep to the Tensor fasciæ latæ is prolonged upwards to lateral part of the capsule of the hip-joint. The greater part of the the Glutæus maximus is inserted into the iliotibial tract. Below, the lata is attached to all the prominent points around the knee-joint, condyles of the femur and tibia, and the head of the fibula. On either of the patella it is strengthened by transverse fibres from the lower the Vasti, which are attached to and support this bone. Of these the are the stronger, and are continuous with the iliotibial tract. The fascia gives off two strong intermuscular septa which are attached to the length of the linea aspera of the femur and its prolongations above below: the lateral and stronger septum, which extends from the inserti the Glutæus maximus to the lateral condyle, separates the Vastus lateralis front from the short head of the Biceps femoris behind, and gives partial to these muscles; the medial and thinner septum separates the Vastus m from the Adductores and the Pectineus. Besides these there are mu smaller septa, separating the individual muscles, and enclosing each distinct sheath.

The **fossa ovalis** (saphenous opening) (fig. 599).—At the upper and part of the thigh, a little below the medial end of the inguinal ligament a large oval aperture in the fascia lata; it transmits the great saphenous vein, and other smaller vessels, and is termed the *fossa ovalis*. The cribrosa, which is pierced by the structures passing through the opening the aperture and must be removed to expose it. The fascia lata in the of the thigh is described as consisting of a superficial and a deep portion.

The *superficial portion* of the fascia lata is the part on the lateral side the fossa ovalis. It is attached to the crest and anterior superior spine of ilium, to the whole length of the inguinal ligament, and to the pecten pubis conjunction with the lacunar ligament. From the tubercle of the os it is reflected downwards and lateralwards, as an arched margin, the *falciform margin*, forming the lateral boundary of the fossa ovalis; this margin over and is adherent to the anterior layer of the sheath of the femoral vessels the fascia cribrosa is attached to it. The upward and medial prolongation the falciform margin is named the *superior cornu*; its downward and medial prolongation, the *inferior cornu*. The latter is well defined, and is continued behind the great saphenous vein with the pectineal fascia.

The *deep portion* is situated on the medial side of the fossa ovalis, and continuous with the superficial portion at the lower margin of the fossa; upwards, it covers the Pectineus, Adductor longus, and Gracilis, and, behind the sheath of the femoral vessels, to which it is closely united continuous with the iliopectineal fascia, and is attached to the pecten pubis.

From this description it may be observed that the superficial portion fascia lata lies in front of the femoral vessels, and the deep portion them, so that an apparent aperture exists between the two, through the great saphenous vein passes to join the femoral vein.

The **Tensor fasciæ latæ** (fig. 598) arises from the anterior 5 cm. of outer lip of the iliac crest; from the outer surface of the anterior superior spine, and part of the outer border of the notch below it, between the Glutæus medius and Sartorius; and from the deep surface of the fascia lata. inserted between the two layers of the iliotibial tract of the fascia lata the junction of the middle with the upper one-third of the thigh.

Nerve-supply.—The Tensor fasciæ latæ is supplied by the fourth and fifth lumbar and first sacral nerves through the superior glutæal nerve.

Actions.—The Tensor fasciæ latæ tightens the fascia lata; continuing its action it abducts the thigh and rotates it inwards. In the erect posture, acting

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

w, it serves to steady the pelvis on the head of the femur; through the iliotibial it steadies the condyles of the femur on the tibia.

The **Sartorius** (figs. 598, 600, 602), the longest muscle in the body, is w and ribbon-like; it arises by tendinous fibres from the anterior superior spine and the upper one-half of the notch below it. It crosses obliquely upper and anterior parts of the thigh, from the lateral to the medial side, descends vertically, as far as the medial side of the knee, passing behind medial condyle of the femur to end in a tendon. This curves obliquely wards and expands into a broad aponeurosis, which is inserted, in front the Gracilis and Semitendinosus, into the upper part of the medial surface the body of the tibia, nearly as far forwards as the anterior crest. The

FIG. 599.—The right fossa ovalis (saphenous opening).

er part of the aponeurosis is curved backwards over the upper edge of tendon of the Gracilis so as to be inserted behind it. An offset, from its er margin, blends with the capsule of the knee-joint, and another, from its er border, with the fascia on the medial side of the leg.

The relations of this muscle to the femoral artery are important, as it constitutes the guide in tying the vessel. In the upper one-third of the thigh it forms the lateral of a triangle, the *femoral* (*Scarpa's*) *triangle*, the medial side of which is formed by the al border of the Adductor longus, and the base by the inguinal ligament; the oral artery passes through the middle of this triangle from its base to its apex. In middle one-third of the thigh, the femoral artery is contained in the *adductor* (*Hunter's*) , on the roof of which the Sartorius lies (fig. 602).

Nerve-supply.—The Sartorius is supplied by the second and third lumbar nerves ugh the femoral nerve.

Actions.—The Sartorius flexes the leg on the thigh, and the thigh on the pelvis; also abducts the thigh and rotates it outwards. Acting from below it flexes the on the thigh and rotates it towards the opposite side.

The **Quadriceps femoris** (figs. 598, 600, 602) is the great extensor of the leg, and consists of a large fleshy mass which covers the front and of the femur. It is subdivided into separate portions, which have no distinctive names. One occupies the middle of the thigh, and arises the ilium; from its straight course it is called the *Rectus femoris*. The three take origin from the body of the femur, which they cover from trochanters to the condyles; that on the lateral side of the femur is the *Vastus lateralis*; that on the medial side, the *Vastus medialis*; that in front, the *Vastus intermedius*.

FIG. 600.—A transverse section through the thigh at the level of the apex of the femoral triangle. Four-fifths of natural size.

The **Rectus femoris** is fusiform in shape, and its superficial fibres are arranged in a bipennate manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: an anterior or straight, from the anterior inferior iliac spine, and a posterior or reflected, from a groove above the brim of the acetabulum. The two unite at an acute angle, and spread into an aponeurosis which is prolonged downwards on the anterior surface of the muscle, and from this the muscular fibres arise. The muscle ends in a broad and thick aponeurosis which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the base of the patella.

The **Vastus lateralis** is the largest part of the Quadriceps femoris. It arises by a broad aponeurosis, which is attached to the upper part of the intertrochanteric line, to the anterior and inferior borders of the great trochanter, to the lateral lip of the gluteal tuberosity, and to the upper one-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the lateral lip of the linea aspera: this aponeurosis covers the upper three-
ths of the muscle, and from its deep surface many fibres take origin. A
additional fibres arise from the tendon of the Glutæus maximus, and
the lateral intermuscular septum between the Vastus lateralis and short
of the Biceps femoris. The fibres form a large fleshy mass, which is
ed to a strong aponeurosis, placed on the deep surface of the lower part
e muscle: this aponeurosis contracts into a flat tendon which is inserted
the lateral border of the patella, blending with the Quadriceps femoris
on, and giving an expansion to the capsule of the knee-joint.

The Vastus medialis and Vastus intermedius appear to be inseparably
ed, but when the Rectus femoris has been reflected a narrow interval will
be observed extending upwards from the medial border of the patella between
two muscles, and the separation may be carried to the lower part of the
trochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus medialis** arises from the lower one-half of the intertrochanteric
the medial lip of the linea aspera, the upper part of the medial supra-
ylar ridge, the tendons of the Adductor longus and Adductor magnus,
the medial intermuscular septum. Its fibres are directed downwards
forwards, and are chiefly attached to an aponeurosis which lies on the
surface of the muscle and is inserted into the medial border of the patella
e Quadriceps femoris tendon, an expansion being sent to the capsule
knee-joint.

The **Vastus intermedius** (Crureus) arises from the front and lateral surfaces
upper two-thirds of the body of the femur, and from the lower part of
lateral intermuscular septum. Its fibres end in a superficial aponeurosis,
forms the deep part of the Quadriceps femoris tendon.

The *tendons* of the different portions of the Quadriceps unite at the lower
of the thigh, to form a single strong tendon which is inserted into the
of the patella, some fibres passing over it to blend with the ligamentum
e. More properly, the patella may be regarded as a sesamoid bone
ped in the tendon of the Quadriceps; and the ligamentum patellæ,
is continued from the apex of the patella to the tuberosity of the tibia,
e proper tendon of insertion of the muscle, the medial and lateral patellar
cula (p. 410) being expansions from its borders. A bursa, which usually
unicates with the cavity of the knee-joint, is situated between the femur
the portion of the Quadriceps tendon above the patella; another is
osed between the ligamentum patellæ and the upper part of the front
e tibia (fig. 522).

The **Articularis genus** (Subcrureus) is a small muscle, usually distinct
the Vastus intermedius, but occasionally blended with it; it consists of
al muscular bundles which arise from the anterior surface of the lower
of the body of the femur, and are inserted into the upper part of the
vial stratum of the articular capsule of the knee-joint.

Nerve-supply.—The Quadriceps femoris and the Articularis genus are supplied
e second, third, and fourth lumbar nerves, through the femoral nerve.

Actions.—The Quadriceps femoris extends the leg upon the thigh. The Rectus
assists the Psoas major and Iliacus in supporting the pelvis and trunk upon
mur; it also assists in flexing the thigh on the pelvis, or if the thigh be fixed
flex the pelvis. The Vastus medialis draws the patella medialwards as well
wards. The Articularis genus pulls upwards the synovial stratum of the
r capsule of the knee-joint during extension of the leg.

Applied Anatomy.—A few fibres of the Rectus femoris are occasionally ruptured from
strain. This accident is especially liable to occur during the games of football and
, and is sometimes known as 'cricket thigh.' The patient experiences a sudden
the part, as if he had been struck, and the Rectus stands out and is felt to be tense
d. The accident is often followed by considerable swelling from inflammatory
. The Quadriceps femoris may be torn away from its insertion into the patella.
dent is caused in the same manner as fracture of the patella by muscular action,
y a violent muscular effort to prevent falling while the knee is in a position of
ction. A distinct gap can be felt above the patella, and, owing to the retraction
muscular fibres, union may fail to take place. The ligamentum patellæ may be
d about 2·5 cm. above the tibia; or the tuberosity of the tibia may be torn
the bone; the last condition is more likely to happen before the ossification of the
ity is completed, i.e. before the age of twenty years.

2. The Medial Femoral Muscles.

Gracilis.	Adductor longus.
Pectineus.	Adductor brevis.

Adductor m

The **Gracilis** (figs. 598, 600, 602) is the most superficial muscle medial side of the thigh. It is thin and flattened, broad above, na tapering below. It arises by aponeurosis from the anterior of the lower one-half of the sy pubis and the upper one-half pubic arch. The fibres run v downwards, and end in a tendon, which passes behind the condyle of the femur, curves r medial condyle of the tibia, becomes flattened, and is inserted the upper part of the medial sur the body of the tibia, below the c A few fibres from the lower the tendon are prolonged into the fascia of the leg. At its insertion tendon is situated immediately that of the Semitendinosus, upper edge is overlapped by the of the Sartorius, with which it is blended. It is separated from the collateral ligament of the knee-j a bursa common to it and the of the Semitendinosus.

Fig. 601.—The deep medial femoral muscles. Right side.

Nerve-supply.—The Gracilis is by the second and third lumbar through the obturator nerve.

Actions.—The Gracilis flexes and rotates it inwards; it also the thigh.

The **Pectineus** (fig. 598) flat, quadrangular muscle, situ the anterior part of the upper medial aspect of the thigh. It from the pecten pubis, and to a extent from the surface of bone in of it, between the iliopectineal e and pubic tubercle, and from the covering the anterior surface muscle; the fibres pass down backwards, and lateralwards, inserted into the femur, along leading from the lesser trocha the linea aspera.*

Relations.—Its *anterior surface* is tion with the fascia lata, which sep from the femoral vessels and great s vein; its *posterior surface*, with the of the hip-joint, the Adductor brevis rator externus, and the anterior b

* The Pectineus may consist of two pletely separated strata: the lateral or stratum, which is constant, is supp branch from the femoral nerve, or absence of this branch by the accesso ator nerve; the medial or ventral strat present, is supplied by the obturator ner M. Paterson, *Journal of Anatomy and Phy*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the obturator nerve; its *lateral border*, with the Psoas major and the medial femoral circumflex vessels; its *medial border*, with the margin of the Adductor longus.

Nerve-supply.—The Pectineus is supplied by the second and third lumbar nerves, through the femoral nerve; and by the third lumbar through the accessory obturator when this nerve is present. Occasionally it receives a branch from the obturator nerve.

Actions.—The Pectineus adducts the thigh and flexes it on the pelvis.

The Adductor longus (figs. 601, 602), the most superficial of the three adductors, is a triangular muscle, lying in the same plane as the Pectineus. It arises by a flat, narrow tendon, from the front of the os pubis in the angle between the crest and the symphysis. It soon expands into a broad fleshy plate which passes downwards, backwards, and lateralwards, and is inserted, by an aponeurosis, into the middle one-third of the linea aspera of the femur, between the Vastus medialis and the Adductor magnus, with both of which it is usually blended.

Relations.—Its *anterior surface* is in relation with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; its *posterior surface*, with the Adductores brevis et magnus, the anterior branch of the obturator nerve, and near its insertion with the profunda femoris vessels; its *lateral border*, with the Pectineus; its *medial border*, with the Gracilis.

Nerve-supply.—The Adductor longus is supplied by the second and third lumbar nerves through the obturator nerve.

Actions.—The Adductor longus adducts the thigh, flexes it on the pelvis, and rotates it outwards.

Applied Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon may be ruptured by suddenly gripping the saddle. Occasionally, especially in cavalry soldiers, the tendon becomes ossified, constituting the 'rider's bone.'

The Adductor brevis (figs. 600, 601) is situated behind the Pectineus and the Adductor longus. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the inferior ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres, passing backwards, lateralwards, and downwards, are inserted by an aponeurosis into the femur, along the line leading from the lesser trochanter to the linea aspera and into the upper part of the linea aspera, immediately behind the Pectineus and the upper part of the Adductor longus.

Relations.—Its *anterior surface* is in relation with the Pectineus, Adductor longus, the profunda femoris, and anterior branch of the obturator nerve; its *posterior surface*, with the Adductor magnus, and posterior branch of the obturator nerve; its *lateral border*, with the medial femoral circumflex artery, the Obturator externus, and conjoined tendon of the Psoas major and Iliacus; its *medial border*, with the Gracilis and Adductor longus. It is pierced near its insertion by the second, or first and second, perforating branches of the arteria profunda femoris.

Nerve-supply.—The Adductor brevis is supplied by the third and fourth lumbar nerves, through the obturator nerve.

Actions.—The Adductor brevis adducts the thigh, flexes it on the pelvis and rotates it outwards.

The Adductor magnus (figs. 600, 601, 602) is a large triangular muscle, situated on the medial side of the thigh. It arises from a small part of the inferior ramus of the os pubis, from the inferior ramus of the ischium, and from the lateral margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are short, horizontal in direction, and are inserted into the rough line leading from the greater trochanter of the femur to the linea aspera, medial to the Glutæus maximus*; those from the ramus of the ischium are directed downwards and lateralwards with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the

* These uppermost fibres are sometimes described as a separate muscle—the *Adductor minimus* which is situated somewhat in front of the other parts of the muscle.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

linea aspera and the upper part of this medial prolongation below. The portion of the muscle, composed principally of the fibres arising from tuberosity of the ischium, forms a thick fleshy mass which descends vertically, and ends about the lower one-third of the thigh in a rounded which is inserted into the adductor tubercle on the medial condyle femur, and is connected by a fibrous expansion to the line leading from the tubercle to the linea aspera. At the insertion of the muscle is a series of osseo-aponeurotic openings, formed by tendinous arches

FIG. 602.—A transverse section through the middle of the thigh. Four-fifths of natural size.

to the bone. The upper four openings are small, and give passage to perforating branches of the arteria profunda femoris. The lowest is of size, and transmits the femoral vessels to the popliteal fossa.

Relations.—Its *anterior surface* is in relation with the Pectineus, Adductores brev longus, the femoral and profunda vessels, and the posterior branch of the obturator a bursa intervenes between the highest part of the muscle and the lesser trochanter femur; its *posterior surface*, with the sciatic nerve, the Glutæus maximus, Biceps fem Semitendinosus, and Semimembranosus. Its *superior border* lies parallel with the ratus femoris, the superficial branch of the medial femoral circumflex artery passing bet them; its *medial border* is in relation with the Gracilis, Sartorius, and fascia lata.

Nerve-supply.—The Adductor magnus is supplied by the third and fourth lum nerves through the obturator nerve, and by a branch from the sacral through the sciatic nerve.

Actions.—The Adductor magnus adducts the thigh and rotates it outwa it also flexes the thigh on the pelvis. The Pectineus and the Adductores ad the thigh powerfully; they are especially used in horse exercise, the sides of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

while being grasped between the knees by the contraction of these muscles; they rotate the thigh outwards, and when the limb has been abducted, they draw it inwards, carrying the thigh across that of the opposite side. In progression, they assist in drawing forwards the lower limb. If the lower extremities be fixed, the muscles, taking their fixed points below, act upon the pelvis, serving to maintain the body in an erect posture; or, if their action be continued, flex the pelvis forwards upon the femur.

3. The Muscles of the Glutæal Region

Glutæus maximus.
Glutæus medius.
Glutæus minimus.
Piriformis.
Obturator externus.
Obturator internus.
Gemellus superior.
Gemellus inferior.
Quadratus femoris.

The **Glutæus maximus** (fig. 603), the largest and most superficial muscle in the glutæal region, is a broad and thick fleshy mass of a quadrilateral shape, and

Fig. 603.—The right glutæus maximus muscle.

forms the prominence of the buttock. Its large size is one of the most characteristic features of the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. The muscle is remarkably coarse in structure, being made up of fasciculi lying parallel with one another, and collected into large bundles separated by fibrous septa. It

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

arises from the posterior glutæal line of the ilium, and the rough portion of the ilium including the crest, immediately above and behind it; from the aponeurosis of the lower part of the Sacrospinalis; from the posterior surface of the sacrum, and from the side of the coccyx; from the sacrotuberous ligament, and from the deep fascia (glutæal aponeurosis) covering the Glutæus medius. The fibres forming the upper part of the muscle run obliquely downwards and lateralwards; those forming the upper and middle portion of the muscle, together with the superficial fibres of the lower part, pass across the greater trochanter, and end in a thick tendinous lamina, which passes across the fascia lata; the deeper fibres of the lower portion of the muscle are inserted into the glutæal tuberosity of the femur between the Vastus lateralis and Adductor magnus.

Three *bursæ* are usually found in relation with the deep surface of the muscle. One, of large size, and generally multilocular, separates it from the greater trochanter; a second, often wanting, is situated on the tuber of the ischium; a third is found between the tendon of the muscle and the Vastus lateralis.

Relations.—Its *superficial surface* is in relation with a thin fascia which separates it from the subcutaneous tissue; its *deep surface*, with the ilium, sacrum, coccyx, sacrotuberous ligament, part of the Glutæus medius, Piriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, greater trochanter, the origin of the Biceps femoris, Semitendinosus, Semimembranosus, and the Adductor magnus. The superficial part of the superior glutæal artery reaches the deep surface of the muscle by passing between the Piriformis and the Glutæus medius; the inferior glutæal, internal pudendal vessels and the sciatic, pudendal, and lateral femoral cutaneous nerves and muscular branches from the sacral plexus, issue from the pelvis below the Piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also found under cover of the lower part of the muscle. Its *upper border* is thin, and is connected with the Glutæus medius by the glutæal aponeurosis. Its *lower border* is free and prominent, and is crossed by the fold of the nates.

Nerve-supply.—The Glutæus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior glutæal nerve.

Actions.—When the Glutæus maximus takes its fixed point from the pelvis it extends the thigh and brings it into line with the trunk. Taking its fixed point below, it supports the pelvis and the trunk upon the head of the femur. Its most powerful action is to raise the trunk after stooping by drawing the pelvis backwards. It is a tensor of the fascia lata, and through the iliotibial tract it steadies the femur on the tibia during standing, when the extensor muscles are relaxed.

The **Glutæus medius** is a broad, thick, radiating muscle, situated on the outer surface of the pelvis. Its posterior one-third is covered by the Glutæus maximus, its anterior two-thirds by the glutæal aponeurosis, which separates it from the superficial fascia and integument. It arises from the outer surface of the ilium between the iliac crest and posterior glutæal line above, and the anterior glutæal line below; it also arises from the strong fascia which covers the upper part of its outer surface. The fibres converge to a flattened tendon which is inserted into the oblique ridge directed downwards and forwards on the lateral surface of the greater trochanter of the femur. A bursa separates the tendon from the surface of the trochanter over which it glides.

Nerve-supply.—The Glutæus medius is supplied by the fourth and fifth lumbar and first sacral nerves, through the superior glutæal nerve.

Actions.—The Glutæus medius abducts the thigh; its anterior fibres rotate the thigh inwards.

The **Glutæus minimus** (fig. 604), the smallest of the Glutæi, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the anterior and inferior glutæal lines, and below from the margin of the greater sciatic notch. The fibres converge to the outer surface of an aponeurosis, and this ends in a tendon which is inserted into a ridge on the lateral part of the anterior surface of the greater trochanter of the femur, and gives an expansion to the capsule of the hip-joint. A bursa is interposed between the tendon and the medial part of the anterior surface of the greater trochanter.

Between the Glutæus medius and Glutæus minimus are the deep branches of the superior glutæal vessels, and the superior glutæal nerve. Deep to the Glutæus minimus are the reflected tendon of the Rectus femoris and the capsule of the hip-joint.

Fig. 604.—The muscles of the glutæal region and the posterior femoral muscles. Right side.

Nerve-supply.—The Glutæus medius is supplied by the fourth and fifth lumbar and first sacral nerves, through the superior glutæal nerve.

Actions. — The Glutæus medius is an abductor of the thigh; its anterior fibres rotate the thigh inwards.

The **Piriformis** (fig. 604) lies almost parallel with the posterior margin of the Glutæus medius. It is situated partly within the pelvis and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to portions of bone between the anterior sacral foramina, and to the grooves leading from the foramina: a few fibres also arise from the margin of the greater sciatic foramen, and from the anterior surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, and is inserted by a rounded tendon into the upper border of the greater trochanter of the femur, behind and above, but partly blended with, the common tendon of the Obturator internus and Gemelli.

Relations.—*Within the pelvis* the *anterior surface* of the Piriformis is in relation with the rectum (especially on the left side), the sacral plexus of nerves, the branches of the hypogastric vessels; its *posterior surface* with the sacrum. *Outside the pelvis*, its *anterior surface* is in contact with the posterior surface of the rectum and capsule of the hip-joint, and its *posterior surface*, with the Glutæus maximus. Its *upper border* is in relation with the Glutæus medius, and the superior glutæal vessels and nerve; its *lower border*, with the Gemelli superior and Coccygeus. Inferior glutæal and internal pudendal vessels, and the sciatic, posterior femoral cutaneous, and pudendal nerves, and muscular branches from the sacral plexus, appear on the buttock between the Piriformis and Gemellus superior. The muscle is frequently pierced by the common

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Nerve-supply.—The Piriformis is supplied by twigs from the first and sacral nerves.

Action.—The Piriformis rotates the thigh outwards.

The **obturator membrane** (fig. 605) is a thin fibrous sheet, which completely closes the obturator foramen. Its fibres are arranged in two bundles mainly transverse in direction; the uppermost bundle is attached to the obturator tubercles and completes the obturator canal for the passage of the obturator vessels and nerve. The membrane is attached to the margin of the obturator foramen except at its lower lateral angle, where it is fixed to the pelvic surface of the inferior ramus of the ischium, i.e. to the margin. Both Obturator muscles are connected with this membrane.

FIG. 605.—The left obturator membrane. External aspect.

The **Obturator internus** (fig. 606) is situated partly within the lesser pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the anterolateral wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the inferior rami of the os pubis and ischium and to the inner surface of the hip-bone below and behind the pelvic brim, reaching from the upper part of the greater sciatic foramen above and behind to the obturator foramen below and in front. It also arises from the medial part of the pelvic surface of the obturator membrane, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve, and to a slight extent from the obturator fascia, which covers the muscle. The fibres converge rapidly towards the lesser sciatic foramen and end in four or five tendinous bands on the deep surface of the muscle; these bands are reflected at a right angle over the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered by synovial cartilage, which is separated from the tendon by a bursa, and presents two or more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite into a single flattened tendon, which passes horizontally across the capsule of the hip-joint, and, after receiving the attachments of the Gemelli, is inserted into the fore part of the medial surface of the greater trochanter of the femur.

The **Gemellus superior**, the smaller of the two, arises from surface of the spine of the ischium, blends with the upper part of of the Obturator internus, and is inserted with it into the medial the greater trochanter of the femur. It is sometimes wanting.

Nerve-supply.—The Gemellus superior is supplied by the fifth lumbar and second sacral nerves, through the nerve to the Obturator internus.

The **Gemellus inferior** arises from the upper part of the tuber the ischium, immediately below the groove for the Obturator intern It blends with the lower part of the tendon of the Obturator intern is inserted with it into the medial surface of the greater trochanter.

Nerve-supply.—The Gemellus inferior is supplied by the fourth and first sacral nerves through the nerve to the Quadratus femoris.

Actions.—The Gemelli superior et inferior rotate the thigh outwards.

Fig. 607.—The left Obturator externus.

The **Quadratus femoris** (fig. 604) is a flat, quadrilateral muscle, betw Gemellus inferior and the upper margin of the Adductor magnus; it is sep from the latter by the superficial branch of the medial femoral circ artery. It arises from the upper part of the external border of the tube of the ischium, and is inserted into the upper part of the linea quadrata femur. A bursa is often found between the front of this muscle and the trochanter.

Nerve-supply.—The Quadratus femoris is supplied by a branch which its fibres from the fourth and fifth lumbar and first sacral nerves.

Action.—The Quadratus femoris is an external rotator of the thigh.

The **Obturator externus** (fig. 607) is a flat, triangular muscle, which the outer surface of the anterior wall of the pelvis. It arises from the of bone immediately around the medial side of the obturator foramen from the rami of the os pubis, and the inferior ramus of the ischium; arises from the medial two-thirds of the outer surface of the obturator brane, and from the tendinous arch which completes the canal for the of the obturator vessels and nerves. The fibres springing from the ramus of the ischium extend on to the inner surface of the bone, where obtain a narrow origin between the margin of the foramen and the attach of the obturator membrane. The fibres converge and pass backwards, wards, and upwards, and end in a tendon which runs across the back neck of the femur and lower part of the capsule of the hip-joint and is into the trochanteric fossa of the femur. The obturator vessels lie be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

muscle and the obturator membrane; the anterior branch of the obturator reaches the thigh by passing in front of the muscle, and the posterior by piercing it.

Nerve-supply.—The Obturator externus is supplied by the third and fourth nerves through the obturator nerve.

Action.—The Obturator externus is an external rotator of the thigh.

4. The Posterior Femoral Muscles (fig. 604)

Biceps femoris. Semitendinosus. Semimembranosus.

The **Biceps femoris** (figs. 600, 602, 604) is situated on the posterolateral back of the thigh. It has two heads of origin: one, the long head, arises from the lower and medial impression on the posterior part of the ischial tuberosity, by a tendon common to it and the Semitendinosus, and from the lower part of the sacrotuberous ligament; the other, the short head, from the lateral lip of the linea aspera of the femur, between the Adductor magnus and Vastus lateralis, extending up almost as high as the insertion of the Gluteus maximus; from the lateral prolongation of the linea aspera to within 5 cm. of the lateral condyle; and from the lateral intermuscular septum. The fibres of the long head form a fusiform belly, which passes downwards and lateralwards across the sciatic nerve to end in an aponeurosis; this aponeurosis covers the posterior surface of the muscle, receives on its deep surface the fibres of the short head, and gradually contracts into a tendon, which is inserted into the lateral side of the head of the fibula, and by a small slip into the lateral condyle of the tibia. This tendon forms the lateral hamstring and divides into two portions which embrace the fibular collateral ligament of the knee-joint; from its posterior border a thin expansion is given off to the fascia of the leg. The common peronæal nerve descends along its medial border.

Nerve-supply.—The Biceps femoris is supplied by the fifth lumbar, and first, second and third sacral nerves; the long head through the tibial nerve, the short head through the common peronæal nerve.

Actions.—The Biceps femoris, acting from above, flexes the leg on the thigh, and when the knee is semiflexed rotates the leg slightly outwards. Acting from below it serves to support the pelvis on the head of the femur and draws the trunk backwards as in raising it from the stooping position.

The **Semitendinosus** (figs. 602, 604), remarkable for the great length of its tendon of insertion, is situated at the posterior and medial aspect of the thigh. It arises from the lower and medial impression on the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps femoris; it also arises from an aponeurosis connecting the adjacent surfaces of the two muscles to the extent of about 7·5 cm. from their origin. The belly is fusiform and ends a little below the middle of the thigh in a long flat tendon which lies along the medial side of the popliteal fossa; the tendon curves around the medial condyle of the tibia, passes over the tibial collateral ligament of the knee-joint, from which it is separated by a bursa, and is inserted into the upper part of the medial surface of the body of the tibia behind the insertion of the Sartorius and below that of the Gracilis. Near its insertion it is united with the tendon of the Gracilis and gives off a prolongation to the deep fascia of the leg. A tendinous intersection is usually observed about the middle of the muscle.

Nerve-supply.—The Semitendinosus is supplied by the fifth lumbar, and first, second and third sacral nerves, through the tibial nerve.

Actions.—Acting from above it flexes the knee-joint, and when the joint is flexed rotates the leg slightly inwards. When its fixed point is below its action is similar to that of the Biceps femoris.

The **Semimembranosus** (figs. 602, 604, 608), so called from its membranous form of origin, is situated at the back and medial side of the thigh. It arises by a thick tendon from the upper and lateral impression on the tuberosity of the ischium, above and lateral to the Biceps femoris and Semitendinosus, and is inserted into the groove on the back of the medial condyle of the tibia.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The tendon of origin expands into an aponeurosis, which passes d under cover of the Semitendinosus and long head of the Biceps femo this aponeurosis muscular fibres arise, and converge to another a which covers the lower part of the posterior surface of the muscle and into the tendon of insertion. The tendon of insertion gives off cert expansions: one, of considerable size, passes upwards and lateral inserted into the back part of the lateral condyle of the femur, for of the oblique popliteal ligament of the knee-joint; a second is downwards to the fascia which covers the Popliteus muscle; while a

FIG. 608.—A transverse section through the thigh, 4 cm. proximal to th adductor tubercle of the femur. Four-fifths of natural size.

join the tibial collateral ligament of the knee-joint and the fascia of th The muscle overlaps the upper part of the popliteal vessels.

The tendons of insertion of the Semitendinosus and Semimembranosu the medial hamstrings.

Nerve-supply.—The Semimembranosus is supplied by the fifth lumbar and second and third sacral nerves through the tibial nerve.

Actions.—The actions of the Semimembranosus are similar to those o Semitendinosus.

Applied Anatomy.—In disease of the knee-joint, contraction of the ham tendons is a frequent complication; this causes flexion of the leg, and a partial dislo of the tibia backwards, with a slight degree of rotation outwards, probably due action of the Biceps femoris. The hamstring tendons occasionally require subcut division in some forms of spurious ankylosis of the knee-joint dependent upon perm contraction and rigidity of the muscles, or from contracture of the ligamentous and tissues surrounding the joint, the result of disease. The relation of the common p nerve, which lies in close apposition to the medial border of the tendon of the femoris, must always be borne in mind in dividing this tendon, and a free incision exposure of the tendon, before division, is the safer proceeding.

In the operation of stretching the sciatic nerve to cure sciatica the tendon of orig the Semimembranosus may be mistaken for the nerve.

III. The Muscles of the Leg

e muscles of the leg may be divided into three groups: anterior, posterior, teral.

1. The Anterior Crural Muscles (fig. 610)

Tibialis anterior.
Extensor hallucis longus.
Extensor digitorum longus.
Peronæus tertius.

The fascia cruris or deep fascia of the leg is continuous above with the ta lata, and is attached around the knee to the patella, the ligamentum lle, the tuberosity and condyles of the tibia, and the head of the fibula.

FIG. 609.—A transverse section through the leg, 9 cm. distal to the knee-joint.

nd, it forms the popliteal fascia which covers the popliteal fossa; here it engthened by transverse fibres, and perforated by the small saphenous It receives an expansion from the tendon of the Biceps femoris laterally, xpansions from the tendons of the Sartorius, Gracilis, Semitendinosus, Semimembranosus medially; it blends with the periosteum covering the utaneous surface of the tibia, and with that covering the head and malleolus the fibula; below, it is continuous with the transverse crural and laciniate ents. It is thick and dense in the upper and anterior part of the leg, and origin, by its deep surface, to some fibres of the Tibialis anterior and sor digitorum longus; it is thinner behind, where it covers the Gastro- nius and Soleus. On the lateral side of the leg it gives off the *anterior* and *rior fibular intermuscular septa* which are attached respectively to the olateral and posterolateral borders of the fibula; in the anterior and rior crural regions the fascia also gives off several slender processes which the individual muscles. A broad transverse intermuscular septum, the *deep transverse fascia of the leg*, intervenes between the superficial deep posterior crural muscles.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Fig. 610.—The right anterior crural muscles.

The **Tibialis anterior** (figs. 609, 610) is situated on the lateral side of the tibia, thick and fleshy above, tendinous below. It arises from the lateral condyle and upper half or two-thirds of the lateral surface of the body of the tibia; from the adjoining part of the anterior surface of the interosseous membrane; from the deep surface of the fascia cruris; and from the intermuscular septum between it and the Extensor digitorum longus. The fibres run vertically downwards, and end in a tendon which is apparent on the lower part of the muscle at the lower end of the leg; after passing through the middle compartments of the transverse and cruciate crural ligaments, it is inserted into the medial and under surfaces of the first cuneiform bone and the base of the first metatarsal bone. This muscle overlaps the anterior tibial vessels and deep peronæal nerve in the upper part of the leg.

Nerve-supply.—The Tibialis anterior is supplied by the fourth and fifth lumbar and first sacral nerves, through the deep peronæal nerve.

Actions.—The Tibialis anterior is a flexor of the ankle-joint; it also raises the medial edge of the foot, i.e. inverts the foot.

The **Extensor hallucis longus** (figs. 609, 615) is a thin muscle, situated between the Tibialis anterior and the Extensor digitorum longus. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, medial to the origin of the Extensor digitorum longus; it also arises from the anterior surface of the interosseous membrane to a similar extent. The anterior tibial vessels and deep peronæal nerve lie between it and the Tibialis anterior. The fibres pass downwards, and end in a tendon, which crosses the anterior border of the muscle, passes through a compartment in the cruciate crural ligament, crosses to the medial side of the anterior tibial vessels near the ankle-joint, and is inserted into the base of the distal phalanx of the great toe. Opposite the metatarsophalangeal articulation a thin prolongation is given off from either side of the tendon to cover the dorsal surface of the joint. The expansion from the medial side of the tendon is usually inserted into the base of the proximal phalanx.

Nerve-supply.—The Extensor hallucis longus is supplied by the fourth and fifth lumbar and first sacral nerves through the deep peronæal nerve.

Actions. — The Extensor hallucis longus extends the phalanges of the great toe; in continued action it flexes the ankle-joint.

The **Extensor digitorum longus** (figs. 609, 610, 615) is a pennate muscle, situated on the lateral part of the front of the leg. It arises from the lateral condyle of the tibia, the upper three-fourths of the anterior surface

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the body of the fibula, the upper part of the anterior surface of the rosseous membrane, the deep surface of the fascia cruris, the anterior fibular rmuscular septum and the septum between it and the Tibialis anterior. ween it and the Tibialis anterior are the upper portions of the anterior vessels and the deep peronæal nerve. The tendon passes under the verse and cruciate crural ligaments in company with the Peronæus tertius, divides into four slips, which run forward on the dorsum of the foot, are inserted into the second and third phalanges of the four lesser toes. tendons to the second, third, and fourth toes are each joined, opposite the tarsophalangeal articulation, on the lateral side by a tendon of the tensor digitorum brevis. The tendons are inserted as follows: each receives rous expansion from the corresponding Lumbricalis and Interossei, and spreads out into a broad aponeurosis, which covers the dorsal surface of first phalanx; at the articulation of the first with the second phalanx this neurosis divides into three slips—an intermediate, which is inserted into the of the second phalanx; and two collateral slips, which, after uniting one another on the dorsal surface of the second phalanx, are inserted the base of the third phalanx.

Nerve-supply.—The Extensor digitorum longus is supplied by the fourth and lumbar and first sacral nerves, through the deep peronæal nerve.

Actions.—The Extensor digitorum longus extends the phalanges of the toes, when its action is continued flexes the ankle-joint.

The **Peronæus tertius** (figs. 610, 615) is a part of the Extensor digitorum is, and might be described as its fifth tendon. The fibres belonging to tendon arise from the lower one-third or more of the anterior surface of fibula, the lower part of the anterior surface of the interosseous mem- e, and the anterior fibular intermuscular septum. The tendon passes er the transverse and cruciate crural ligaments in the same compartment the Extensor digitorum longus, and is inserted into the dorsal surface of base of the fifth metatarsal bone, but often spreads into a thin sheet h extends forwards along the shaft of the bone. This muscle is some- s wanting.

Nerve-supply.—The Peronæus tertius is supplied by the fourth and fifth lumbar first sacral nerves, through the deep peronæal nerve.

Actions.—The Peronæus tertius flexes the ankle-joint; it also raises the al border of the foot, i.e. everts the foot.

2. The Posterior Crural Muscles

The muscles of the back of the leg are subdivided into two groups—superficial deep. Those of the superficial group constitute a powerful muscular forming the calf of the leg. Their large size is one of the most acteristic features of the muscular apparatus in man, and bears a direct on to his erect attitude and his mode of progression.

Superficial Group (fig. 611).

Gastrocnemius. Soleus. Plantaris.

The **Gastrocnemius** (figs. 609, 611) is the most superficial of the group, forms the greater part of the calf. It arises by two heads, which are ected to the condyles of the femur by strong, flat tendons. The medial larger head takes its origin from a depression at the upper and posterior of the medial condyle behind the adductor tubercle, and from a rounded cle on the popliteal surface of the femur just above the medial condyle. lateral head arises from an impression on the lateral surface of the lateral yle and from the lower part of the corresponding epicondylar ridge. Both s also arise from the subjacent part of the articular capsule of the knee Each head spreads out into a tendinous expansion which covers the rior surface of the corresponding part of the muscle. From the anterior aces of these tendinous expansions, muscular fibres are given off; those of medial head being thicker and extending lower than those of the lateral

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The fibres unite at an angle in the middle line of the muscle, in a te raphe which expands into a broad aponeurosis on the anterior surface muscle, and into this the remaining fibres are inserted. The apo gradually contracting, unites w tendon of the Soleus, and forms with the tendo calcaneus.

FIG. 611.—The right posterior crural muscles. Superficial group.

Relations.—The fascia cruris separ *superficial surface* of the muscle from saphenous vein, and the peronæal and medial sural cutaneous, and sural nerves common peronæal nerve crosses the lat of the muscle, lying partly under cover of femoris. The *deep surface* is in relat the oblique popliteal ligament of the kn the Popliteus, Soleus, Plantaris, vessels, and tibial nerve. In front tendon of the medial head is a bursa, some cases, communicates with the ca the knee-joint. The tendon of the latera sometimes contains a sesamoid fibrocart bone, where it plays over the corresp condyle; and one is occasionally found in tendon of the medial head.

Nerve-supply.—The Gastrocnem supplied by the first and second nerves, through the tibial nerve.

Actions.—Acting from above the Ga nemius extends the ankle-joint; acting below it flexes the knee-joint.

The **Soleus** (figs. 609, 611) is a flat muscle situated immediately in of the Gastrocnemius. It arises by dinous fibres from the back of the and from the upper one-fourth of posterior surface of the body, of the fi from the popliteal line and the m one-third of the medial border of the ti and from a fibrous band which stre between these origins and arches over popliteal vessels and tibial nerve. muscular fibres end in a flat tendon w covers the posterior surface of the mu and, gradually becoming thicker narrower, joins with the tendon of Gastrocnemius, and forms with it the te calcaneus.

Relations.—Its *superficial surface* is in tion with the Gastrocnemius and Plantar *deep surface*, with the Flexor digitorum Flexor hallucis longus, Tibialis posteri posterior tibial vessels and nerve, from which it is separated by the deep tra fascia of the leg.

Nerve-supply.—The Soleus is supplied the first and second sacral nerves throug tibial nerve.

Actions.—The Soleus is an extensor of the ankle-joint; in standing, Soleus, taking its fixed point from below, steadies the leg on the foot.

The Gastrocnemius and Soleus together form a muscular mass which occasionally described as the *Triceps suræ*; its tendon of insertion is the te calcaneus.

The **tendo calcaneus** (tendo Achillis) (fig. 611), the common tendo the Gastrocnemius and Soleus, is the thickest and strongest in the body.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

...15 cm. long, and begins near the middle of the leg, but receives fleshy ...on its anterior surface, almost to its lower end. It gradually narrows and ...ons until it reaches a level about 4 cm. above the calcaneus; below this ...it expands and is inserted into the middle part of the posterior surface ...calcaneus, a bursa being interposed between the tendon and the upper ...of this surface.

...ctions.—The muscles of the calf—Gastrocnemius and Soleus—are the chief ...sors of the ankle-joint. They possess considerable power, and are called into ...in standing, walking, dancing, and leaping; hence the large size they usually ...ent. In walking, these muscles raise the heel from the ground; the body being ...supported on the raised foot, the opposite limb can be carried forwards.

The **Plantaris** (fig. 611) arises from the lower part of the lateral prolonga- ...of the linea aspera, and from the oblique popliteal ligament of the knee-joint. ...ms a small fusiform belly, from 7 cm. to 10 cm. long; this ends in a long ...r tendon which crosses obliquely between the Gastrocnemius and Soleus, ...l runs along the medial border of the tendo calcaneus, to be inserted with ...g the posterior part of the calcaneus. This muscle is sometimes double, ...at other times wanting. Occasionally, its tendon is lost in the laciniate ...ment, or in the fascia of the leg.

...erve-supply.—The Plantaris is supplied by the fourth and fifth lumbar and ...acral nerves, through the tibial nerve.

...ctions.—The Plantaris is the rudiment of a large muscle, the tendon of which ...ce of the lower animals is inserted into the plantar aponeurosis: in man it ...an accessory to the Gastrocnemius, extending the ankle-joint if the foot be free, ...ing the knee-joint if the foot be fixed.

Deep Group (fig. 612)

Popliteus.
Flexor hallucis longus.
Flexor digitorum longus.
Tibialis posterior.

The **deep transverse fascia** of the leg is a septum between the superficial ...deep muscles of the back of the leg. At the sides it is connected to the ...al margin of the tibia and the posterolateral border of the fibula. Above, ...re it covers the Popliteus, it is thick and dense, and receives an expansion ...the tendon of the Semimembranosus; it is thin in the middle of the ...; but below, where it covers the tendons passing behind the malleoli, it ...ck and continuous with the laciniate ligament.

The **Popliteus** (fig. 612) is a thin, flat, triangular muscle, which forms the ...of the lower part of the popliteal fossa. It arises by a strong tendon ...2·5 cm. long, from a depression at the anterior part of the groove on ...lateral condyle of the femur, and to a small extent from the oblique ...al ligament of the knee-joint. It is inserted into the medial two-thirds ...e triangular surface above the popliteal line on the posterior surface of ...dy of the tibia, and into the tendinous expansion covering the muscle.

...ctions.—Its tendon of origin is covered by the tendon of the Biceps femoris and by ...ular collateral ligament of the knee-joint: it grooves the posterior border of the ...meniscus, and is invested by the synovial stratum of the capsule of the knee-joint. ...ascia covering the muscle separates it from the Gastrocnemius, Plantaris, popliteal ...s, and tibial nerve. The deep surface of the muscle is in contact with the oblique ...al ligament of the knee-joint and the back of the tibia.

...erve-supply.—The Popliteus is supplied by the fourth and fifth lumbar and ...acral nerves, through the tibial nerve.

...ctions.—The Popliteus flexes the knee-joint; when the joint is flexed, it ...s the tibia inwards. It is specially called into action at the beginning of ...n of the knee-joint inasmuch as it produces the slight inward rotation of the ...which is essential in the early stage of this movement.

The **Flexor hallucis longus** (figs. 612, 615) is situated on the fibular side ...leg. It arises from the inferior two-thirds of the posterior surface of the ...of the fibula, with the exception of about 2·5 cm. at its lowest part; from ...lower part of the interosseous membrane; from the posterior fibular inter- ...ular septum, and from the fascia covering the Tibialis posterior. The fibres ...obliquely downwards and backwards, and end in a tendon which occupies ...the whole length of the posterior surface of the muscle. This tendon lies

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in a groove which crosses the posterior surface of the lower end of the the posterior surface of the talus, and the under surface of the sustentaculum tali of the calcaneus. In the sole of the foot it runs forwards between the two heads of Flexor hallucis brevis, and is inserted into the base of the distal phalanx of the great toe. The grooves on the talus and calcaneus, which contain the tendon of the muscle, are converted by tendinous fibres into a canal which is lined by a mucous sheath. As the tendon passes forwards in the sole of the foot, it is situated medially and crosses from the lateral to the medial side of, the tendon of the Flexor digitorum longus, with which it is connected by a fibrous slip.

FIG. 612.—The right posterior crural muscles. Deep group.

Relations.—Its *superficial surface* is in relation with the Soleus and tendo calcaneus, from which it is separated by the deep transverse fascia; its *deep surface*, with the fibula, Tibialis posterior, the peronæal vessels, the lower part of the interosseous membrane, and the ankle-joint; its *lateral border*, with the Peronæi; its *medial border*, with the Tibialis posterior, posterior tibial vessels and tibial nerve.

Nerve-supply.—The Flexor hallucis longus is supplied by the fifth lumbar and first and second sacral nerves, through the tibial nerve.

Actions.—The Flexor hallucis longus flexes the great toe, and, continuing its action, extends the ankle-joint.

The **Flexor digitorum longus** (fig. 613) is situated on the tibial side of the leg. At its origin it is thin and pointed, but it gradually increases in size as it descends. It arises from the posterior surface of the body of the tibia, medial to the tibial origin of the Tibialis posterior; this origin extends from immediately below the popliteal line to within 7 cm. or so of the lower extremity of the bone; it also arises from the fascia covering the Tibialis posterior. The fibres end in a tendon, which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the medial malleolus, in a groove common to it and the Tibialis posterior, but separated from the latter by a fibrous septum; the tendon being contained in a special compartment lined by a separate mucous sheath. It passes obliquely forwards and laterally in contact with the medial side of the sustentaculum tali (fig. 613), and deep to the laciniate ligament, and enters the sole of the foot (fig. 620), where it crosses below (or superficial to) the tendon of the Flexor hallucis longus, and receives from it a strong slip. It then expands and is joined by the Quadratus plantæ, and finally divides into four tendons which are inserted into the bases of the distal phalanges of the second, third, fourth, and fifth toes, each tendon passing through an opening in the corresponding tendon of the Flexor digitorum brevis opposite the base of the first phalanx.

Relations.—In the leg its *superficial surface* is in relation with the posterior tibial vessels and tibial nerve, and the deep transverse fascia which separates it from the Soleus; its *deep surface*, with the tibia and Tibialis posterior. In the foot, it is covered

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Abductor hallucis and Flexor digitorum brevis, and crosses superficial to the
hallucis longus.

Nerve-supply.—The Flexor digitorum longus is supplied by the fifth lumbar and
ral nerves through the tibial nerve.

Action.—The Flexor digitorum longus flexes the phalanges of the toes, and in
ed action extends the ankle-joint. In consequence of the oblique direc-
of its tendons it draws the toes medialwards, but this is counteracted by the
rsus plantæ which is inserted into the lateral side of the tendon.

Fig. 613.—A coronal section through the right talocrural and talocalcaneal joints.

Tibialis posterior (figs. 609, 612) lies between the Flexor hallucis
and Flexor digitorum longus, and is the deepest muscle on the back of
g. It begins above by two pointed processes, separated by an angular
l through which the anterior tibial vessels pass to the front of the leg.
es from the posterior surface of the crural interosseous membrane,
the exception of its lowest part; from the lateral portion of the posterior
e of the body of the tibia, between the commencement of the popliteal
ve and the junction of the middle with the lower one-third of the body
; and from the upper two-thirds of the medial surface of the fibula;
s also arise from the deep transverse fascia, and from the inter-
r septa separating it from the adjacent muscles. In the lower one-
of the leg its tendon passes in front of that of the Flexor digitorum
and lies with it in a groove behind the medial malleolus, but enclosed
parate sheath; it next passes under the laciniate and over the deltoid
t into the foot, and then below the plantar calcaneonavicular ligament,
it contains a sesamoid fibrocartilage. It is inserted into the tuberosity
avicular bone, and gives off fibrous slips, one of which passes backwards
attached to the sustentaculum tali of the calcaneus, while others pass
ch and lateralwards and are fixed to the three cuneiform bones, the
l bone, and the bases of the second, third, and fourth metatarsal bones.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Relations.—Its *superficial surface* is in relation with the Soleus, from w separated by the deep transverse fascia, the Flexor digitorum longus, the post vessels and tibial nerve, and the peronæal vessels; its *deep surface* with the in membrane, the tibia, fibula, and ankle-joint.

Nerve-supply.—The Tibialis posterior is supplied by the fifth lumbar and sacral nerves through the tibial nerve.

Actions.—The Tibialis posterior extends the ankle-joint; it also pu medial border of the foot, i.e. inverts the foot. In the sole of the foot it lies directly below the plantar calcaneonavicular ligament, and is an im factor in maintaining the longitudinal arch of the foot.

3. The Lateral Crural Muscles (fig. 614)

Peronæus longus. Peronæus brevis.

The **Peronæus longus** (figs. 609, 612, 614) is situated at the upper pa lateral side of the leg, and is the more superficial of the two muscles. It from the head and upper two-thirds of the lateral surface of the body

Fig. 614.—The right lateral crural muscles.

Digitized by Arya Samaj Foundation Chennai and eGangotri

from the deep surface of the fascia, and from the anterior and posterior intermuscular septa: occasionally also by a few fibres from the lateral side of the tibia. Between its attachments to the head and body of the there is a gap through which the common peronæal nerve passes to the front of the leg. It ends in a long tendon, which runs behind the lateral malleolus, in a groove common to it and the tendon of the Peronæus brevis, in which it lies; the groove is converted into a canal by the superior peronæal retinaculum, and the tendons in it are contained in a common mucous sheath. The tendon then extends obliquely forwards across the lateral side of the calcaneus, below the trochlear process and the tendon of the Peronæus tertius, and under cover of the inferior peronæal retinaculum; it crosses the lateral side of the cuboid bone, and then runs on the under surface of that bone in a groove which is converted into a canal by the long plantar ligament.

FIG. 615.—A transverse section through the leg, 6 cm. proximal to the tip of the medial malleolus.

then crosses the sole of the foot obliquely, and is inserted by two slips (a) the lateral side of the base of the first metatarsal bone and (b) the medial side of the first cuneiform bone; occasionally a third slip is attached to the base of the second metatarsal bone. The tendon changes its direction two points: (a) below the lateral malleolus, (b) on the cuboid bone; in both these situations it is thickened, and, in the latter, a sesamoid fibro-cartilage (sometimes a bone) is usually developed in its substance.

Nerve-supply.—The Peronæus longus is supplied by the fourth and fifth lumbar and first sacral nerves through the superficial peronæal nerve.

Actions.—The Peronæus longus extends the ankle-joint and everts the foot. As a consequence of the oblique direction of its tendon across the sole it is an important agent in maintaining the transverse arch of the foot. Taking its fixed point on the Peronæus longus serves to steady the leg on the foot; this is especially of use in standing on one leg, when the tendency of the superincumbent weight to throw the leg medialwards; the Peronæus longus overcomes this tendency by pulling on the lateral side of the leg.

The **Peronæus brevis** (figs. 614, 615) arises from the lower two-thirds of the lateral surface of the body of the fibula, in front of the Peronæus longus; from the anterior and posterior fibular intermuscular septa. The fibres run vertically downwards, and end in a tendon which runs behind the lateral

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

malleolus along with, but in front of, that of the Peronæus longus, the two being enclosed in the same compartment, and lubricated by a common sheath. It then runs forwards on the lateral side of the calcaneus, above the trochlear process and the tendon of the Peronæus longus, and is inserted into the tuberosity at the base of the fifth metatarsal bone, on its lateral side.

On the lateral surface of the calcaneus the tendons of the Peronæus longus et brevis occupy separate osseo-aponeurotic canals formed by the retinacula and the inferior peronæal reticulum; each tendon is enveloped by a sheath, prolongation of the common mucous sheath.

Nerves.—The Peronæus brevis is supplied by the fourth and fifth lumbar and first sacral nerves through the superficial peronæal nerve.

Action.—The Peronæus brevis extends the foot upon the leg.

Applied Anatomy.—Rigidity and contraction of the tendons of the various muscles of the leg give rise to one or other of the kinds of deformity known as *club foot*. The simple and common deformity, and one that is rarely, if ever, congenital, is *talipes equinus*, the heel being raised by the rigidity and contraction of the Gastrocnemius, so that the patient walks upon the ball of the foot. A condition of temporary talipes equinus is often produced by the weight of the bed-clothes in patients, particularly children, who have been kept lying on their backs in bed for a few weeks. In this case, unless a cradle is used to protect the feet, the weight of the bed-clothes will cause them extended, causing a temporary shortening of the calf-muscles that will prevent the patient from flexing the ankles to anything less than a right angle, and will produce the characteristic shuffling gait when he first gets up and walks. In *talipes varus*, the sole is forcibly adducted and the medial side of the sole raised, sometimes to a right angle, from the ground, by the action of the Tibiales anterior et posterior. In *talipes valgus* the lateral edge of the foot is raised by the Peronæi, and the patient walks on the medial side of the foot. In *talipes calcaneus* the toes are raised by the extensor muscles, the heel depressed and the patient walks upon it. Other varieties of deformity are met with, as *talipes equinovarus*, *equinovalgus*, and *calcaneovalgus*, names which sufficiently indicate their nature. Of these, talipes equinovarus is the most common congenital form. The heel is raised by the tendo calcaneus, the medial border of the foot drawn upwards by the Tibialis anterior, the anterior two-thirds twisted medialwards by the Tibialis posterior, and the arch increased by the contraction of the plantar aponeurosis, so that the patient walks on the middle of the lateral border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia; by this means the foot regains its proper position, and the tendons heal by the organization of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow sharp-pointed knife inserted beneath it.

Rupture of a few of the fibres of the Gastrocnemius, or rupture of the Plantaris tendon, not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn-tennis, and is hence known as 'lawn-tennis leg.' The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo calcaneus is also sometimes ruptured. It is stated that John Hunter ruptured his tendo calcaneus while dancing, at the age of forty. The bursa between the tendo calcaneus and the posterior surface of the calcaneus sometimes becomes inflamed, especially in pedestrians and 'long-distance' walkers. It causes great and disabling pain, and entirely prevents the sufferer from continuing his walk.

THE FASCIA ROUND THE ANKLE

Fibrous bands, thickened portions of fascia, bind down the tendons in front of and behind the ankle in their passage to the foot. They consist of the transverse crural, cruciate crural, and laciniate ligaments, and the superior and inferior peronæal retinacula.

The **transverse crural ligament** (upper part of anterior annular ligament) (figs. 610, 616) binds down the tendons of the Tibialis anterior, Extensor hallucis longus, Extensor digitorum longus and Peronæus tertius as they descend on the front of the tibia and fibula; the anterior tibial vessels and the deep peronæal nerve also pass under cover of it. It is attached laterally to the lower end of the fibula, and medially to the tibia; above, it is continuous with the fascia of the leg.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The cruciate crural ligament (lower part of anterior annular ligament) (610, 616) is a Y-shaped band placed in front of the ankle-joint. The of the Y is attached to the upper surface of the calcaneus, in front of sulcus calcanei; it is directed medialwards in front of the tendons of the

Fig. 616.—The mucous sheaths of the tendons round the right ankle. Lateral aspect. (From a specimen prepared by J. C. B. Grant.)

Fig. 617.—The mucous sheaths of the tendons round the right ankle. Medial aspect. (From a specimen prepared by J. C. B. Grant.)

Peronæus tertius and Extensor digitorum longus and divides into two limbs. The limb is directed upwards and medialwards, to be attached to the tibial malleolus, passing over the Extensor hallucis longus and the anterior tibial vessels and deep peronæal nerve, but enclosing the Tibialis anterior by splitting into two laminæ. The other limb extends downwards and medialwards to be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

attached to the plantar aponeurosis; it crosses the tendons of the Ex hallucis longus and Tibialis anterior, the arteria dorsalis pedis, a terminal branches of the deep peronæal nerve.

The **laciniate ligament** (internal annular ligament) extends fr tibial malleolus above to the margin of the calcaneus below; its upper is continuous with the deep fascia of the leg, its lower with the aponeurosis and the fibres of origin of the Abductor hallucis muscle. It a series of bony grooves in this situation into canals for the passage tendons of the flexor muscles into the sole of the foot and also affords pro to the posterior tibial vessels and tibial nerve as they enter the sole foot. From the medial to the lateral side, these structures lie in the fo order: tendon of the Tibialis posterior, tendon of the Flexor digitorum posterior tibial vessels and tibial nerve, and tendon of the Flexor longus.

The **peronæal retinacula** are fibrous bands which retain the tend the Peronæi longus et brevis in position as they cross the lateral side ankle. The *superior retinaculum* (external annular ligament) is att above to the lateral malleolus and below to the lateral surface of the calc The *inferior retinaculum* is continuous in front with the cruciate crural ligam behind it is attached to the lateral surface of the calcaneus; some of its are fixed to the trochlear process of the calcaneus, forming a septum betw the tendons of the Peronæi longus et brevis.

The **mucous sheaths of the tendons round the ankle.**—The te crossing the ankle-joint are enclosed in mucous sheaths. On the *front* ankle (fig. 616) the sheath for the Tibialis anterior extends from the margin of the transverse crural ligament to the interval between the div limbs of the cruciate ligament; those for the Extensor digitorum l and Extensor hallucis longus reach upwards to just above the level malleoli, the former being the higher. The sheath of the Extensor ha longus is prolonged on to the base of the first metatarsal bone, while of the Extensor digitorum longus reaches only to the level of the base fifth metatarsal bone. On the *medial side* of the ankle (fig. 617) the sheat the Tibialis posterior extends for about 4 cm. above the malleolus; belo ends just short of the insertion of the tendon into the tuberosity of the navi bone. The sheath for the Flexor hallucis longus reaches up to the lev the malleolus, while that for the Flexor digitorum longus is slightly hig the former is continued to the base of the first metatarsal bone, but the l ends opposite the navicular bone.

On the *lateral side* of the ankle (fig. 616) a sheath, which is single for greater part of its extent, encloses the Peronæi longus et brevis. It exte upwards for about 4 cm. above the tip of the malleolus and downwards forwards for about the same distance.

IV. The Muscles of the Foot

1. The Dorsal Muscle of the Foot

Extensor digitorum brevis

The **fascia** on the dorsum of the foot (fascia dorsalis pedis) is a membranous layer, continuous above with the transverse and cruciate cru ligaments; on either side it blends with the plantar aponeurosis; anteri it forms a sheath for the tendons on the dorsum of the foot.

The **Extensor digitorum brevis** (figs. 610, 616) is a thin muscle, wh arises from the forepart of the upper and lateral surface of the calcaneus front of the groove for the Peronæus brevis; from the lateral talocalcan ligament, and the stem of the cruciate crural ligament. It passes oblique forwards and medialwards across the dorsum of the foot, and ends in tendons. The medial part of the muscle is usually a more or less distinct ending in a tendon which crosses the dorsalis pedis artery and is inserted the dorsal surface of the base of the first phalanx of the great toe; it sometimes described as a separate muscle—the *Extensor hallucis brevis*.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

three tendons are inserted into the lateral sides of the tendons of the Extensor digitorum longus of the second, third, and fourth toes.

Nerve-supply.—The Extensor digitorum brevis is supplied by the fourth and lumbar and first sacral nerves through the deep peronæal nerve.

Actions.—The Extensor digitorum brevis extends the phalanges of the four toes on which it is inserted, but, in the great toe, acts only on the first phalanx.

2. The Plantar Muscles of the Foot

The **plantar aponeurosis** (fig. 618) is of great strength, and consists of white fibres disposed, for the most part, longitudinally: it is divided into central, lateral, and medial portions.

Fig. 618.—The plantar aponeurosis of the right foot.

The *central portion*, the thickest, is narrow behind, and attached to the medial process of the tuberosity of the calcaneus, posterior to the origin of the Flexor digitorum brevis; it becomes broader and thinner in front, and divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes splits opposite the metatarsophalangeal articulation into two strata, superficial and deep. The superficial stratum

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is inserted into the skin of the transverse sulcus which separates the to the sole. The deep stratum divides into two slips which embrace th of the flexor tendons of the toes, and blend with the sheaths of the t and with the transverse metatarsal ligament, thus forming a series of through which the tendons of the short and long flexors pass to t Through the intervals between the five processes the digital vessels a and the tendons of the Lumbricales are transmitted. At the point of of the aponeurosis are numerous transverse fasciculi which bind the together, and connect them with the integument. The central p the plantar aponeurosis is continuous with the lateral and medial porti sends upwards into the foot, at the lines of junction, two vertical inter septa, which separate the intermediate from the lateral and medial g plantar muscles; from these vertical septa thinner transverse septa are which separate the different layers of muscles in this region. The deep of the central part of the aponeuro origin behind to the Flexor dig brevis.

FIG. 619.—The plantar muscles of the right foot. First layer.

The *lateral portion* covers the und face of the Abductor digiti quinti thin in front and thick behind, w forms a strong band between the process of the tuberosity of the ca and the base of the fifth metatarsal it is continuous medially with the portion, and laterally with the fas salis pedis.

The *medial portion* is thin, and the under surface of the Abductor ha it is continuous behind with the la ligament, medially with the fascia d pedis, and laterally with the central p of the plantar aponeurosis.

The muscles in the plantar reg the foot may be divided into medial, l and intermediate groups; but for criptive purposes it is more convenie divide them into four layers, in the in which they are successively expo dissecting this region.

The First Layer (fig. 619)

Abductor hallucis.
Flexor digitorum brevis.
Abductor digiti quinti.

The **Abductor hallucis** (fig. 619 along the medial border of the foot covers the origins of the plantar v and nerves. It arises from the m process of the tuberosity of the calca the laciniate ligament, the plantar a eurosis, and the intermuscular se between it and the Flexor digitorum b The fibres end in a tendon which is inse together with the medial tendon of Flexor hallucis brevis, into the medial s of the base of the first phalanx of the g toe.

Nerve-supply.—The Abductor hallucis is supplied by the fifth lumbar and sacral nerves, through the medial plantar nerve.

Actions.—The Abductor hallucis flexes the proximal phalanx of the great and draws it medialwards.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Flexor digitorum brevis** (fig. 619) lies immediately above the central part of the plantar aponeurosis. Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia. It arises by a narrow process, from the medial process of the tuberosity of the calcaneus, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and the adjacent muscles. It divides into four tendons, one for each of the four lesser toes. Opposite the bases of the first phalanges, each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor digitorum longus; the two slips then unite, partially ensheathe, and form a grooved channel for the reception of the tendon of the Flexor digitorum longus. The tendon divides again and is inserted into the sides of the second phalanx about its middle. The mode of division of the tendons of the Flexor digitorum brevis, and of their insertion into the phalanges, is analogous to that of the tendons of the Flexor digitorum sublimis in the hand.

Nerve-supply.—The Flexor digitorum brevis is supplied by fifth lumbar and first sacral nerves, through the medial plantar nerve.

Actions.—The Flexor digitorum brevis flexes the second phalanges upon the first; continuing its action it flexes the first phalanges and brings the toes together.

The fibrous sheaths of the flexor tendons (fig. 619).—The terminal portions of the tendons of the long and short flexor muscles are contained in fibro-aponeurotic canals similar in their arrangement to those in the fingers. These canals are bounded above by the phalanges, and below by fibrous bands, which arch across the tendons, and are attached on either side to the margins of the phalanges. Opposite the bodies of the proximal and second phalanges the fibrous bands (*vaginal ligaments*) are strong, and the fibres are transverse; but opposite the joints they are much thinner, and the fibres are directed obliquely. Each canal contains a mucous sheath, which is reflected on the contained tendons; within this sheath are *vincula tendinum* arranged similarly to those in the fingers.

The **Abductor digiti quinti** (fig. 619) lies along the lateral border of the foot, and its medial margin is in relation with the lateral plantar vessels and nerve. It arises from the lateral and medial processes of the tuberosity of the calcaneus, from the under surface of the bone between the processes, from the plantar aponeurosis, and from the intermuscular septum between it and the Flexor digitorum brevis. Its tendon glides over a smooth facet on the inferior surface of the base of the fifth metatarsal bone and is inserted, with the tendon of the Flexor digiti quinti brevis, into the lateral side of the base of the first phalanx of the fifth toe.

Nerve-supply.—The Abductor digiti quinti is supplied by the first and second sacral nerves through the lateral plantar nerve.

Actions.—The Abductor digiti quinti flexes the proximal phalanx of the little toe and draws it lateralwards.

The Second Layer (fig. 620)

Quadratus plantæ. Lumbricales.

The **Quadratus plantæ** (Flexor accessorius) (fig. 620) arises by two heads, which are separated from each other by the long plantar ligament: the medial, larger, head is muscular, and is attached to the medial concave surface of the calcaneus, below the groove for the tendon of the Flexor hallucis longus; the lateral head, flat and tendinous, arises from the calcaneus in front of the medial process of its tuberosity, and from the long plantar ligament. The two heads join at an acute angle, and end in a flattened band which is inserted into the inferior surface and lateral margin of the tendon of the Flexor digitorum longus, forming a kind of groove in which the tendon is lodged. It usually sends slips to those tendons of the Flexor digitorum longus which pass to the second, third, and fourth toes.

Nerve-supply.—The Quadratus plantæ is supplied by the first and second sacral nerves, through the lateral plantar nerve.

Actions.—The Quadratus plantæ assists the Flexor digitorum longus and converts the oblique pull of the tendons of that muscle into a direct backward pull on the toes.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Lumbricales** (fig. 620) are four small muscles, accessory to the t of the Flexor digitorum longus, and numbered from the medial side of the they arise from these tendons, as far back as their angles of separation springing from two tendons, except the first, which arises only from the m border of the first tendon of the Flexor digitorum longus. The muscle in tendons, which pass forwards on the medial sides of the four lesser and are inserted into the expansions of the tendons of the Extensor digi longus on the dorsal surfaces of the first phalanges.

FIG. 620.—The plantar muscles of the right foot. Second layer.

FIG. 621.—The plantar muscles of right foot. Third layer.

Nerve-supply.—The first Lumbricalis is supplied by the fifth lumbar and f sacral nerves through the medial plantar nerve; the others by the first and secon sacral nerves through the lateral plantar nerve.

Actions.—The Lumbricales flex the proximal phalanges, and by th insertions into the tendons of the Extensor digitorum longus, extend the mi and terminal phalanges.

The Third Layer (fig. 621)

Adductor hallucis.
Flexor hallucis brevis.
Flexor digiti quinti brevis.

The **Flexor hallucis brevis** (fig. 621) arises by a pointed tendinous ...ss from the medial part of the under surface of the cuboid bone, from ...e contiguous portion of the third cuneiform bone, and from the part of the ...ion of the Tibialis posterior which is attached to that bone. It divides ...o a medial and a lateral portion, and the tendons of these are inserted into ...e corresponding sides of the base of the first phalanx of the great toe, a ...sesamoid bone being present in each tendon at its insertion. The medial ...ion is blended with the Abductor hallucis previous to its insertion; the ...eral with the Adductor hallucis. The lateral portion of the Flexor hallucis ...evis is sometimes described as the *first plantar interosseous* muscle.

Nerve-supply.—The Flexor hallucis brevis is supplied by the fifth lumbar and ...st sacral nerves, through the medial plantar nerve.

Action.—The Flexor hallucis brevis flexes the proximal phalanx of the great toe.

The **Adductor hallucis** (fig. 621) arises by two heads—oblique and ...nsverse. The *oblique head* springs from the bases of the second, third, ...fourth metatarsal bones, and from the sheath of the tendon of the Peronæus ...gus, and is inserted, together with the lateral portion of the Flexor hallucis ...evis, into the lateral side of the base of the first phalanx of the great toe. ...e *transverse head* (Transversus pedis), a narrow, flat fasciculus, arises from ...e plantar metatarsophalangeal ligaments of the third, fourth, and fifth toes ...metimes only from the third and fourth), and from the transverse meta-...sal ligament. It is inserted into the lateral side of the base of the first ...alanx of the great toe, its tendon of insertion blending with that of the ...ique head.

Nerve-supply.—The Adductor hallucis is supplied by the first and second sacral ...ves, through the lateral plantar nerve.

Actions.—The oblique head of the Adductor hallucis is chiefly concerned in ad-...ting, but it also assists in flexing, the great toe; the transverse head approximates ...e ties and thus increases the curve of the transverse arch of the metatarsus.

The **Flexor digiti quinti brevis** (fig. 621) arises from the base of the ...th metatarsal bone, and from the sheath of the Peronæus longus; its tendon ...serted into the lateral side of the base of the first phalanx of the fifth toe. ...sionally a few of the deeper fibres are inserted into the lateral part of the ...al one-half of the fifth metatarsal bone; these are described by some as ...stinct muscle, the *Opponens digiti quinti*.

Nerve-supply.—The Flexor digiti quinti brevis is supplied by the first and second ...al nerves, through the lateral plantar nerve.

Action.—The Flexor digiti quinti brevis flexes the little toe.

The Fourth Layer.

Interossei.

The Interossei in the foot are similar to those in the hand, but are grouped ...n either side of the middle line of the *second* digit, instead of that of the *third*. ...ey consist of a dorsal and a plantar set.

The **Interossei dorsales** (fig. 622), four in number, are situated between ...e metatarsal bones. They are bipennate muscles, each arising by two heads ...m the adjacent sides of the metatarsal bones between which it is placed; ...e tendons are inserted into the bases of the first phalanges, and into the ...oneuroses of the tendons of the Extensor digitorum longus. The first ...serted into the medial side of the second toe; the other three into the ...eral sides of the second, third, and fourth toes. In the angular interval ...ween the heads of each of the three lateral muscles, one of the perforating ...eries passes to the dorsum of the foot; through the space between the ...ads of the first muscle the deep plantar branch of the dorsalis pedis artery ...ches the sole of the foot.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **Interossei plantares** (fig. 623), three in number, lie beneath the bones of the foot, rather than between the metatarsal bones, and each is connected with the medial sides of the bodies of the metatarsal bone. They arise from the bases and medial sides of the bodies of the third, fourth, and fifth metatarsal bones, and are inserted into the medial sides of the bases of the first phalanges of the same toes, and into the aponeuroses of the tendons of the Extensor digitorum longus.

Nerve-supply.—The Interossei dorsales et plantares are supplied by the first and second sacral nerves, through the lateral plantar nerve. The first Interosseous dorsalis frequently receives an extra filament from the medial branch of the peronæal nerve on the dorsum of the foot, and the second Interosseous dorsalis receives a twig from the lateral branch of the same nerve.

Fig. 622.—The Interossei dorsales of the left foot. Dorsal aspect.

Fig. 623.—The Interossei plantares of the left foot. Plantar aspect.

Actions.—The Interossei dorsales are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe medialwards, the second muscle draws the same toe lateralwards, and the third and fourth draw the third and fourth toes lateralwards. They assist in flexing the first and extending the second and third phalanges. The Interossei plantares adduct the third, fourth, and fifth toes towards the imaginary line passing through the second toe, and, by means of their insertions into the aponeuroses of the Extensor tendons, assist in flexing the proximal phalanges and extending the middle and terminal phalanges.

Applied Anatomy.—The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fracture are selected for illustration and description.

In fracture of the *neck of the femur inside the articular capsule* (fig. 624), the characteristic signs are slight shortening of the limb, and eversion of the foot, neither of which may appear until some time after the injury. The eversion is caused by the weight of the limb rotating it outwards. The shortening is produced by the contraction of all the muscles about the joint. The fragment which carries the head of the femur receives its nutrition through the vessels in the ligamentum teres.

In fracture of the *femur just below the trochanters* (fig. 625), the upper fragment is drawn forwards almost at right angles with the pelvis, by the Psoas major and Iliacus; and at the same time, everted and abducted by the external rotator muscles and Glutæi, causing a marked prominence at the upper and lateral side of the thigh, and much pain from the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and laceration of the muscles. The limb is shortened, because the lower fragment is upwards by the Rectus femoris in front, and the Biceps femoris, Semimembranosus, Semitendinosus behind; it is, at the same time, everted.

FIG. 624.—A fracture of the neck of the femur within the articular capsule.

FIG. 625.—A fracture of the femur below the trochanters.

FIG. 626.—A fracture of the femur above the condyles.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Oblique fracture of the femur *immediately above the condyles* (fig. 626) is a fa injury, and attended with considerable displacement. On examination of the lower fragment may be felt deep in the popliteal fossa, being drawn backwa Gastrocnemius, and upwards by the hamstrings and Rectus femoris, and in the the fragment may compress the popliteal artery and so cause gangrene. The end of the upper fragment is drawn medialwards by the Pectineus and Addu tilted forwards by the Psoas major and Iliacus, piercing the Rectus, and occa integument.

In transverse fracture of the *patella* (fig. 627) the fragments are separated by of the Quadriceps femoris and by the effusion which takes place into the joint; of separation of the two fragments depending upon the degree of laceration of mentous structures around the bone.

Fig. 628.—An oblique fracture the body of the tibia.

Fig. 627.—A fracture of the patella.

Oblique fracture of the *body of the tibia* (fig. 628). If the fracture takes place obl from above, downwards and forwards, the fragments ride over one another, the fragment being drawn backwards and upwards by the powerful action of the mus the calf; the pointed extremity of the upper fragment projects forwards immed beneath the integument, often protruding through it, and rendering the fracture pound. If the direction of the fracture is the reverse of that shown in the figure pointed extremity of the lower fragment projects forwards, rising up on the lower the upper one.

Fracture of the *fibula with dislocation of the foot lateralwards*, commonly known as 'P fracture,' is one of the most frequent injuries in the region of the ankle-joint. The is fractured about 7 or 8 cm. above the ankle; in addition to this the medial malleo broken off, or the deltoid ligament torn through, and the talus displaced from the sponding surface of the tibia. The foot is markedly everted, and the sharp edge upper end of the fractured malleolus presses strongly against the skin; at the same the heel is drawn up by the muscles of the calf.

ANGIOLOGY

THE vascular system is divided for descriptive purposes into (*a*) the *blood-vascular system*, comprising the heart and blood-vessels through which the blood circulates;* and (*b*) the *lymph-vascular system*, consisting of lymph-vessels and lymphatic vessels, through which a colourless fluid, the lymph, circulates. The two systems communicate with each other and are intimately associated developmentally.

The heart, the central organ of the blood-vascular system, is situated within the thorax. It is a muscular bag, by the contraction of which the blood is propelled to all parts of the body through a complicated series of tubes, termed vessels. The arteries undergo enormous ramification in their course throughout the body, and end in minute vessels, called *arterioles*, which open into a fine-meshed network of microscopic vessels, termed *capillaries*. After the blood has passed through the capillaries it is collected into a series of minute vessels called *venules*, and which join with one another to form *veins*: the veins unite with one another, and ultimately two large venous trunks, named the superior and inferior venæ cavæ, are formed which return the blood to the heart. While the blood is passing through the capillaries a transudation of certain of its fluid elements takes place into the tissue-spaces; this fluid is collected by the lymphatic vessels, and returned to the large veins at the base of the neck. The passage of the blood through the heart and blood-vessels is termed the *circulation* of the blood, of which the following is an outline.

The heart is divided into right and left halves, and each half consists of two cavities, an atrium and a ventricle, which communicate freely with one another; the atria are receiving chambers and the ventricles distributing chambers. The right atrium and ventricle form the right half, and the left atrium and ventricle the left half of the heart; the right half contains venous or impure blood; the left, arterial or pure blood. From the cavity of the left ventricle the arterial or pure blood is carried into a large artery, the branches of which it is distributed to all parts of the body, with the exception of the lungs. As the blood traverses the capillaries of the body it gives up to the tissues the materials necessary for their growth and nourishment, and receives from the tissues the waste products resulting from their metabolism. In doing so it is changed from arterial into venous blood, and the latter is returned by the veins to the right atrium of the heart. From this cavity the venous blood passes into the right ventricle, and from it is conveyed through the pulmonary arteries to the lungs, where it becomes arterialised, and is carried thence to the left atrium by the pulmonary veins. From the left atrium it passes into the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or *systemic* circulation, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or *pulmonary* circulation.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is conveyed by the *portal vein* to the liver. In the liver this vein divides like an artery, and ultimately ends in capillary-like vessels (sinusoids), from which

* The blood is described on pp. 26 to 28.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the rootlets of the *hepatic veins* arise; the hepatic veins carry the bl the inferior vena cava which conveys it to the right atrium. Fro will be understood that the blood supplied to the above-named viscera through two sets of minute vessels before reaching the inferior ve (1) the capillaries in the spleen, pancreas, stomach, &c., draining into the hepa portal vein, and (2) the sinusoids in the liver, draining into the

The **structure of the arteries** (figs. 629, 630).—The wall of an artery of three coats, an internal or *tunica intima*, a middle or *tunica media*, and or *tunica adventitia*. The external coat is tougher than the other two, ruptured when a ligature is tied round the vessel, and, in virtue of their become retracted from the site of the ligature.

The *tunica intima* consists of (*a*) an internal layer of flattened cells, (*b*) these, a small quantity of loose connective tissue, and (*c*) an elastic lami flattened or endothelial cells are in shape with the long axis of the long axis of the blood-vessel cell possesses a nucleus, and is att adjacent cells by cement-substance reduces silver nitrate. The co tissue layer is very thin, and c branched cells, and, in the larger ar fine elastic fibres. The elastic la built up of longitudinally arrange fibres fused together, and is fenestrated, having round or ov tures at irregular intervals. In a verse section of an artery it as a characteristic wavy line, o the contracted condition of the vessel.

Fig. 629.—A transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. × 350. (Klein and Noble Smith.)

A. Artery; *a*, tunica adventitia; *e*, endothelium resting on the elastic lamina; *m*, tunica media.

V. Vein; *a*, tunica adventitia; *m*, tunica media; *e*, endothelium.

The *tunica media*, in the smal medium-sized arteries, consists pri of smooth muscular fibres arrange larly round the vessel; the fibre well-marked, rod-shaped nuclei. smallest arteries the middle coat is composed of smooth muscular (fig. 630). In medium-sized arteri 631) there are in addition elastic and fine elastic membranes lying b the layers of muscular fibres. I larger arteries, as the iliac and c the proportion of elastic tissue is increased, and in the aorta relatively thick elastic laminæ form the greater the thickness of the middle coat.

The *tunica adventitia* consists mainly of fine and closely felted bundles of connective tissue; in all but the smallest arteries it contains some elastic The elastic tissue is most abundant next the tunica media, and it is so described as forming here, between the adventitia and media, a special the *tunica elastica externa*; this layer is most marked in arteries of m size. In the largest vessels the external coat is relatively thin. From the m sized to the smaller arteries it diminishes gradually in thickness; in the s arteries the elastic fibres are wanting, and the connective tissue, of which th is composed, becomes more homogeneous the nearer it approaches the ca and is gradually reduced to a thin membranous envelope, which finally disa

Some arteries have extremely thin walls in proportion to their size; especially the case in those situated within the cranium and vertebral canal the external and middle coats of the arteries are reduced in thickness.

The arteries, in their distribution throughout the body, are enclos thin fibro-areolar *sheaths*. An artery is loosely connected with its shea delicate areolar tissue; and the sheath usually encloses the accompanying and sometimes a nerve. Some arteries, as those in the cranium, are dev sheaths.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The larger arteries are supplied with blood-vessels. These nutrient vessels, called the *vasa vasorum*, arise from branches of the artery itself, or of a neighbouring trunk at some considerable distance from the parts at which they are distributed; they ramify in the loose areolar tissue surrounding the artery with its sheath, and are distributed to the external coat; in general they do not penetrate the other coats; but in some of the larger mammals these vessels have been traced into the middle coat. Minute veins return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymphatic vessels are also present in the outer coat.

Arteries are also supplied with nerves, which form intricate plexuses upon the coats of the larger trunks, and run with the smaller arteries as single cords, or bundles of filaments. Most of the nerve-fibres are non-medullated, and are derived from the sympathetic; but some are medullated. The non-medullated fibres are mostly efferent, and lie in the middle coat. The medullated fibres are believed to be afferent and are distributed to the outer and inner coats. Pacinian corpuscles are occasionally found in the outer coat of the aorta.

vessels named *capillaries* which are interposed between the arterioles and the and constitute a network, the branches of which maintain the same throughout.

The *diameters* of the capillaries vary in the different tissues of the usual size being about 8 μ when the blood is circulating. The smallest in the brain and in the mucous membrane of the intestines; the larg skin, and in the marrow of bone, where they may have a diameter of 20 μ.

The *form* of the capillary network varies in the different tissues, the mes generally round or elongated. Round or angular meshes are most com prevail where there is a dense network, as in the lungs, in most glands and membranes, and in the cutis. Elongated meshes occur in muscles and nerves axis of the mesh running parallel with that of the muscle or nerve. Some capillaries have a looped arrangement, as in the papillae of the tongue and

The number of the capillaries and the size of the meshes determine the of vascularity of a part; the smallest meshes are found in the lungs and chorioid coat of the eye. As a general rule, the more active the functio organ, the closer is its capillary net and the larger its supply of blood. Few vessels are present in tendons, because in the latter little organic change after their formation.

The **structure of the capillaries.**—The wall of a capillary consists of flatte joined edge to edge by cement-substance, and continuous with the endothel which line the arteries and veins. When with nitrate of silver the material which u edges of the epithelial cells is display showing the outlines of the cells (fig. 632). cells are of large size and of an irregular p or lanceolate shape, each containing a nucleus which may be displayed by car hæmatoxylin. Between their edges, at points of their meeting, roundish dark sp sometimes seen, which have been desc stomata, though they are closed by inte substance. By some they are believed the situations through which the colourl puscles of the blood, when migrating fro blood-vessels, emerge; but this view universally accepted.

Fig. 632.—Capillaries from the mesentery of a guinea-pig, after treatment with a solution of nitrate of silver.

a. Cells. *b*. Their nuclei.

In developing capillaries, and in the ca of the glomeruli of the kidneys, the intesti and the chorioid coat of the eye, inter cement cannot be demonstrated, and th are believed to form a syncytium.

In many situations a delicate sheath or e of branched nucleated connective tissue found around the simple capillary tubes, cularly the larger ones; and in other especially in the glands, the capillaries are with retiform connective tissue.

The **sinusoids.**—In the heart, the liver, the suprarenal and parathyreoid the glomera carotica and glomus coccygeum, the smallest blood-vessels diffe true capillaries. They are wider, with an irregular lumen, and have no com tissue covering, their endothelial cells being in direct contact with the cells organ. Moreover, their walls are often incomplete. These vessels have been *sinusoids* by Minot. They are formed by columns of cells or trabeculæ their way into a large blood-vessel or blood-space and carrying its endo before them; at the same time the wall of the vessel or space grows out the columns of cells.

The **structure of the veins.**—The walls of the veins, like those of the are composed of three coats—internal, middle, and external; and these are the necessary modifications, analogous to the coats of the arteries; the in being the endothelial, the middle the muscular, and the external the com tissue or areolar (fig. 629). The main difference between the veins and the is in the comparative thickness of the middle coat in the former.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In the smallest veins the three coats are hardly to be distinguished (fig. 630). endothelium is supported on a membrane separable into two layers, the outer which is the thicker, and consists of a delicate, nucleated membrane (tunica intima), while the inner is composed of a network of longitudinal elastic fibres (tunica media). In the veins next above these in size (0·4 mm. in diameter), a connective tissue layer containing numerous smooth muscular fibres circularly disposed can be traced, forming the middle coat, while the elastic and connective tissue elements of the outer coat are more distinctly perceptible. In the middle-sized veins (fig. 633) the endothelium is of the same character as in the arteries, but nuclei are shorter and broader. It is supported by a connective tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of elastic fibres disposed in the form of a network in place of the infinite fenestrated membrane seen in arteries. This constitutes the *tunica intima*. The *tunica media* is composed of a thick layer of connective tissue with elastic fibres, interspersed, in some veins, with a layer of smooth muscular fibres arranged circularly. The white fibres are in considerable excess, and the elastic fibres are in much greater proportion in the veins than in the arteries. The *tunica adventitia* consists, as in the arteries, of areolar tissue with longitudinal elastic fibres.

FIG. 633.—A transverse section through the wall of a femoral vein of a dog. ×250. The elastic tissue is not differentiated in this preparation.

In the largest veins from two to five times thicker than the tunica media, and contains a large number of longitudinal muscular fibres. These are most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the portal vein, and in the external renal, and azygos veins. In the inferior vena cava, renal and portal veins they extend through the whole thickness of the outer coat, but in the other veins a layer of connective and elastic tissue is found external to the muscular coat. The large veins which open into the heart are covered for a short distance by a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting—(1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater; (3) in the veins of the retina; (4) in the veins of the spongy substance of bones; (5) in the cavernous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an endothelial lining supported on one or more layers of areolar tissue.

Most veins are provided with *valves* which serve to prevent the reflux of the blood. Each valve is formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and is covered on both surfaces by endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The valves are semilunar. They are attached by their convex edges to the wall of the vein; the concave margins are directed in the course of the venous current, and lie in close apposition with the wall of the vein as long as the current of blood takes its natural course; however, any regurgitation takes place, the valves become distended, their free edges are brought into contact, and the current is interrupted. The attached side of the vein on the cardiac side of the attachment of each valve is expanded

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

into a pouch or sinus, which gives to the vessel, when injected or distended, blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially in the veins of the lower extremities, these vessels to conduct the blood against the force of gravity. They are absent in the small veins, i.e. those less than 2 mm. in diameter, also in the venæ cavæ, the renal, uterine, and ovarian veins. The cerebral and spinal veins, the veins of cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. A few valves are found in each renal vein, and one also at its point of junction with the renal vein or inferior vena cava respectively. A few valves are occasionally found in the azygos and hemiazygos veins. Valves are present in the tributaries of the portal vein in the foetus for a short time after birth; as a rule they soon atrophy and disappear, but sometimes they persist in a degenerate form.

The larger veins, like the arteries, are supplied with nutrient vessels, *vasorum*. Nerves also are distributed to the veins in the same manner as the arteries, but in much less abundance.

The Thoracic Cavity

The heart and lungs are situated within the thorax, the walls of which afford them protection. The heart lies between the two lungs, and is enclosed in a fibrous bag, the *pericardium*, while each lung is covered with a serous membrane, the *pleura*; the space between the pleural membranes is called the *mediastinal cavity*. The skeleton of the thorax, and the shape and boundaries of the cavity, have already been described (p. 193).

The **cavity of the thorax**.—The capacity of the thoracic cavity does not correspond with its apparent size externally, because (1) the lower part of the space enclosed by the ribs is occupied by some of the abdominal viscera, and (2) the thoracic cavity extends for a short distance into the neck above the anterior parts of the first ribs. During life the size of the thoracic cavity is constantly varying with the movements of the ribs and Diaphragm, and with the degree of distension of the abdominal viscera.

The **upper opening of the thorax**.—The parts which pass through the upper opening of the thorax are, from before backwards in or near the middle line, the Sternohyoideus and Sternothyreoideus muscles, the remains of the thymus, the inferior thyreoid veins, the trachea, œsophagus, thoracic duct, and the Longus colli muscles; laterally the innominate veins, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary arteries and the costocervical trunks, the vagus, cardiac, phrenic and sympathetic nerves, the greater parts of the anterior divisions of the thoracic nerves, and the left recurrent nerve. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the level of the sternal end of the first rib.

The **lower opening of the thorax** is wider transversely than from before backwards. It slopes obliquely downwards and backwards, so that the thoracic cavity is much deeper behind than in front. The Diaphragm (p. 195) closes the opening and forms the floor of the thorax. The floor is higher at the centre than at the sides, and higher on the right side than on the left; in the dead body the right side reaches the level of the upper border of the fifth costal cartilage, while the left extends only to the corresponding part of the sixth costal cartilage. From the highest point on either side the floor slopes suddenly downwards to the costal and vertebral attachments of the Diaphragm; this slope is more marked behind than in front, so that only a narrow space is left between the Diaphragm and the posterior wall of the thorax.

The Pericardium

The **pericardium** (fig. 634) is a conical fibroserous sac which contains the heart and the roots of the great vessels. It is placed in the mediastinal cavity behind the sternum and the cartilages of the third, fourth, fifth, sixth

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

fourth ribs of the left side, and in front of the thoracic vertebræ, from the fifth to the eighth inclusive.

In front, it is separated from the anterior wall of the thorax, in the greater part of its extent, by the lungs and pleuræ; but a small area, usually corresponding with the left half of the lower part of the body of the sternum, and the internal ends of the cartilages of the fourth and fifth ribs of the left side, has a direct relationship with the chest-wall. Until puberty or adolescence

FIG. 634.—The posterior wall of the pericardial sac, showing the lines of reflection of the serous pericardium on to the great vessels.

lower end of the thymus is in contact with the front of the upper part of the pericardium. *Behind*, the pericardium rests upon the bronchi, the œsophagus, the œsophageal plexus of nerves, the descending thoracic aorta, and the posterior part of the mediastinal surface of each lung. *Laterally*, it is covered by the pleuræ, and is in relation with the mediastinal surfaces of the lungs; the phrenic nerve, with its accompanying vessels, descends between the pericardium and the mediastinal pleura on either side.

The structure of the pericardium.—Although the pericardium is usually described as a single sac, an examination of its structure shows that it consists partially of two sacs intimately connected with one another, but totally different in structure. The outer sac, known as the *fibrous pericardium*, consists of fibrous tissue. The inner sac, or *serous pericardium*, is a delicate membrane

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which lies within the fibrous sac and lines its walls; it is composed of a layer of flattened cells resting on loose connective tissue. The heart-tube the wall of the serous sac from above and behind, and practically obl its cavity, the space being a potential one.

The *fibrous pericardium* forms a flask-shaped bag, the neck of closed by its continuity with the external coats of the great vessels base is attached to the central tendon and to the muscular fibres of half of the Diaphragm. In some of the lower mammals the base completely separated from the Diaphragm or joined to it by some loose tissue; in man much of its diaphragmatic attachment consists of loose tissue which can be readily broken down, but over a small area the tendon of the Diaphragm and the pericardium are fused. Above, the pericardium not only blends with the external coats of the great ves is continuous with the pretracheal layer of the fascia colli (deep cervical By means of these upper and lower connexions it is securely anchored the thoracic cavity. It is also attached to the posterior surface of the by a *superior* and an *inferior sternopericardial ligament*; the superior to the manubrium, and the inferior to the xiphoid process.

The vessels receiving prolongations from the fibrous pericardium the aorta, the superior vena cava, the right and left pulmonary arteries the four pulmonary veins. The inferior vena cava enters the pericardium through the central tendon of the Diaphragm, and receives no covering from the fibrous layer.

The *serous pericardium* is, as already stated, a closed sac which lines fibrous pericardium and is invaginated by the heart; it therefore consists of a *visceral* and a *parietal* portion. The visceral portion, or *epicardium*, the heart and the great vessels, and from the latter is continuous with parietal layer which lines the fibrous pericardium. The portion which the vessels is arranged in the form of two tubes. The aorta and pulmonary artery are enclosed in one tube, the *arterial mesocardium*. The superior inferior venæ cavæ and the four pulmonary veins are enclosed in a tube, the *venous mesocardium*, the attachment of which to the parietal is ∩-shaped. The cul-de-sac between the limbs of the ∩ lies behind the atrium and is known as the *oblique sinus*, while the passage between venous and arterial mesocardia—i.e. between the aorta and pulmonary in front and the atria behind—is termed the *transverse sinus*.

The ligament of the left vena cava.—Between the left pulmonary and subjacent pulmonary vein is a triangular fold of the serous pericardium known as the *ligament of the left vena cava* (vestigial fold of Marshall), formed by the duplicature of the serous layer over the remnant of the part of the left duct of Cuvier (left superior vena cava) (p. 127). This becomes obliterated during fœtal life, and remains as a fibrous band stretching from the upper part of the left superior intercostal vein to the back of left atrium, where it is continuous with a small vein, the *oblique vein of left atrium* (oblique vein of Marshall), which opens into the coronary (fig. 637).

The *arteries* of the pericardium are derived from the internal mammary and their musculophrenic branches, and from the descending thoracic aorta *nerves* are derived from the vagus and phrenic nerves, and the sympathetic trunk.

Applied Anatomy.—Effusion of fluid into the pericardial sac often occurs in rheumatism or pneumonia, or in patients with chronic vascular and renal disease, embarrassing the heart's action and giving rise to signs of cardiac distress, such as pallor, and feeble pulse, dyspnœa, and restlessness. On examination, the apical cardiac impulse is absent, or replaced by a more extensive indefinite and wavering pulsation; it appear to be in the second, third, or fourth left space, and is then not an apex-beat as Potain has stated, but due to the impact of some portion of the heart-wall near base. In children the precordial intercostal spaces may bulge outwards. The striking sign, however, is the great increase in all directions of the precordial dulness percussion. This becomes pear-shaped, the stalk of the pear reaching up to about left sternoclavicular articulation; the dulness also extends some distance to the right the sternum, particularly in the fifth interspace (Rotch). The fluid collects mainly either side of the heart, and below it, especially on the left side, where the Diaphragm yield more readily to pressure than it can on the right. Ewart has drawn attention to presence of a square patch of dulness over the base of the left lung behind, reaching

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the level of the ninth or tenth rib, and extending laterally as far as the inferior angle of the scapula; the underlying lung-tissue gives the physical signs of compression or collapse.

Paracentesis of the pericardium and withdrawal of the fluid within it is sometimes necessary to relieve embarrassment of the heart's action. The puncture may be made in the fifth or sixth left intercostal space near the sternum, with care to avoid wounding the internal mammary artery that usually runs 1·25 cm. lateral to the sternal edge. Alternatively the exploring needle may be entered at the left costoxiphoid angle, and passed upwards and backwards into the pericardial sac. Curschmann recommends paracentesis in or lateral to the left mammary line in the fifth or sixth left interspace, in view of the fact that the fluid tends to collect on either side of and below the heart rather than in front of it.

Pericardiotomy is required when the effusion is of a purulent nature. In this operation a portion of the fifth or sixth costal cartilage is excised. An incision is made along the left border of the sternum from the upper border of the fourth cartilage to the seventh. The fifth costal cartilage is now separated from the sternum and raised, the tissues beneath it being peeled off, so as to avoid wounding the internal mammary artery or the pleura. The fibres of the Transversus thoracis are then separated close to the sternum, and the pericardium felt for and opened, the finger guarding the pleura and left internal mammary artery.

Cardiolysis, or the operation of opening the pericardial sac and dividing adhesions between its visceral and parietal layers, is one that appears to have much to recommend it on clinical grounds. In practice, however, it has rarely proved satisfactory, owing to the great toughness and extent of the adhesions when they are present, and the free hæmorrhage that occurs when they are divided.

The Heart (Cor)

The heart is a muscular bag of a somewhat conical form; it lies between the lungs in the middle mediastinal cavity (fig. 635), and is enclosed in the

Fig. 635.—The heart and lungs. Anterior aspect.

...ium. It is placed obliquely in the chest behind the body of the ...m and adjoining parts of the rib cartilages, and projects farther into

Digitized by Arya Samaj Foundation Chennai and eGangotri

the left than into the right half of the thoracic cavity, so that about one-th of it is situated on the right and two-thirds on the left of the median plane.

Size.—The heart of the adult measures about 12 cm. from base to ap 8 to 9 cm. transversely at the broadest part, and 6 cm. anteroposteriorly. Its weight, in the male, varies from 280 to 340 grammes; in the female, from to 280 grammes. It continues to increase in weight and size up to an advan period of life, and this increase is more marked in men than in women.

Component parts.—As already stated (p. 567) the heart is divided four chambers, viz. right and left atria, and right and left ventricles: the sion is indicated on the surface of the heart by grooves or sulci. The are separated from the ventricles by the *coronary sulcus* (auriculoventric groove); this sulcus contains the trunks of the coronary vessels of the he

FIG. 636.—A section through the heart, showing the ventricular septum.

and is deficient in front, where it is crossed by the root of the pulmonary ar The *interatrial groove*, separating the two atria, is scarcely marked on posterior surface, while anteriorly it is hidden by the pulmonary artery aorta. The ventricles are separated by two grooves, one of which, the *longitudinal sulcus*, is situated on the sternocostal surface of the heart its left margin, the other, the *posterior longitudinal sulcus*, on the diaphrag surface near the right margin; these grooves extend from the base ventricular portion to a notch, the *incisura apicis cordis*, situated a li the right of the apex of the heart.

The *base* (fig. 637) is somewhat quadrilateral in form; it looks up backwards, and to the right, and is separated from the fifth, sixth, seven eighth thoracic vertebræ by the pericardium, œsophagus, aorta, and th duct. It is formed mainly by the left atrium, and, to a small extent, b posterior part of the right atrium. It is in relation above with the bifurc of the pulmonary artery, and is bounded below by the posterior part coronary sulcus, containing the coronary sinus. On the right it is limi the sulcus terminalis of the right atrium, and on the left by the ligament cava and the oblique vein of the left atrium. The four pulm either side, open into the left atrium, whilst the superior

ss into the upper part, and the inferior vena cava into the lower part, right atrium. The portion of the left atrium between the openings of and left pulmonary veins constitutes the anterior wall of the oblique the pericardium (p. 576).

upper, formed by the left ventricle, is directed downwards, forwards, the left, and is overlapped by the left lung and pleura: it lies behind left intercostal space, about 8 cm. from the mid-sternal line, or, in the about 4 cm. below and 2 cm. to the medial side of the left mammary

sternocostal surface (fig. 638) is directed forwards, upwards, and to It consists of an atrial and a ventricular portion, the former being and to the right, the latter below and to the left, of the anterior part

FIG. 637.—The base and the diaphragmatic surface of the heart.

coronary sulcus. The atrial portion is almost entirely formed by the atrium; the greater part of the left atrium is hidden by the ascending and pulmonary artery (fig. 638), and only a small part of its auricula forwards on the left side of the pulmonary artery. About two-thirds ventricular part are formed by the right, and one-third by the left, the line of separation between the ventricles being marked by the longitudinal sulcus. The sternocostal surface lies behind the body of sternum, the Transversus thoracis muscles and the cartilages of the third, fifth, and sixth ribs; owing to the bulging of the heart towards the a much larger part of the surface lies behind the left than the right cartilages. The sternocostal surface is also covered by the pleuræ and anterior parts of the lungs, with the exception of a small triangular corresponding with the cardiac notch in the left lung. The base of area is represented by a line on the middle of the sternum from the of the fourth costal cartilages to the junction of the body of the sternum the xiphoid process, and the sides by lines from the apex of the heart to upper and lower ends of the base line.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The *diaphragmatic surface* (fig. 637), directed downwards and backwards, is formed by the ventricles (chiefly by the left ventricle), and upon the central tendon and a small part of the left muscular portion of the Diaphragm. It is separated from the base by the posterior part of the coronary sulcus, and is traversed obliquely by the posterior longitudinal sulcus.

The *right margin* of the heart, formed by the right atrium, is nearly almost vertical; it is situated behind the third, fourth, and fifth right costal cartilages 1·25 cm. from the margin of the sternum.

The *inferior or acute margin*, formed almost entirely by the right ventricle, is nearly horizontal, and extends from the sternal end of the sixth right costal cartilage to the apex of the heart.

FIG. 638.—The sternocostal surface of the heart.

The *left or obtuse margin* is full and rounded; it is formed mainly by the left ventricle, but to a slight extent, above, by the left auricula. It extends from a point in the second left intercostal space, about 2 cm. from the sternal margin, obliquely downwards, with a convexity to the left, to the apex of the heart.

The atrial septum.—A partition, named the *atrial septum* (figs. 636, 642), intervenes between the right and left atria, and is so obliquely placed that the right atrium lies in front and to the right of the left atrium.

The ventricular septum.—The right ventricle is separated from the left by the *ventricular septum* (figs. 636, 642), which slopes obliquely from the left backwards and towards the right, and is curved with the convexity towards the right ventricle: its margins correspond with the anterior and posterior longitudinal sulci on the surface of the heart. The greater portion of the septum is thick and muscular, and constitutes the *muscular ventricular septum*, but its upper and posterior part, which separates the aortic vestibule from the lower part of the right atrium and upper part of the right ventricle, is thin and fibrous, and is termed the *membranous ventricular septum*. A communication may exist between the ventricles at this part, owing to defective development of the membranous septum.

The right atrium (figs. 639, 642) consists of two parts: a principal cavity or sinus venarum, situated posteriorly, and an anterior, smaller portion, the auricula.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The *sinus venarum* is the large quadrangular pouch placed between the venæ cavæ. Its walls, which are extremely thin, are connected below the right ventricle, and medially with the left atrium.

The *auricula* is a small, conical, muscular pouch, the margins of which are dentated edge. It projects from the upper and front part of the venarum forwards and towards the left side, overlapping the root of the (fig. 638).

The separation of the auricula from the sinus venarum is indicated, on outer surface of the atrium, by a groove, the *sulcus terminalis*, which extends the front of the superior vena cava to the front of the inferior vena cava, represents the line of union of the sinus venosus of the embryo with the

FIG. 639.—The interior of the right side of the heart.

tive atrium. On the inner surface of the atrium the separation is marked vertical, smooth, muscular ridge, the *crista terminalis*. Behind the crista nalis the internal surface of the atrium is smooth, while in front of it the ular fibres of the wall are raised into parallel ridges resembling the teeth comb, and hence named the *musculi pectinati*.

The interior of the right atrium (fig. 639) presents the following parts for mination:

Orifices:
- Superior vena cava.
- Inferior vena cava.
- Coronary sinus.
- Foramina venarum minimarum.
- Right atrioventricular.

Valves:
- Valve of the inferior vena cava.
- Valve of the coronary sinus.

Fossa ovalis.
Limbus fossæ ovalis.
Intervenous tubercle.
Musculi pectinati.
Crista terminalis.

The *superior vena cava* (fig. 638) returns the blood from the upper half of body, and opens into the upper and posterior part of the atrium. Its orifice ected downwards and forwards, and has no valve.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The *inferior vena cava* (fig. 639), larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the right atrium near the atrial septum; its orifice, directed upwards and backwards, is guarded by a rudimentary valve, the *valve of the inferior vena cava* (valve of Eustachius). The blood entering the atrium through the superior vena cava is directed downwards and forwards towards the atrioventricular orifice, while that entering through the inferior vena cava is directed upwards and backwards towards the atrial septum. This is the normal direction of the two streams in fœtal life.

The *coronary sinus* (fig. 637) returns the greater part of the blood from the substance of the heart. Its opening is placed between the orifice of the inferior vena cava and the atrioventricular opening, and is protected by a semilunar circular valve, the *valve of the coronary sinus* (valve of Thebesius).

The *foramina venarum minimarum* are the orifices of minute veins (*venæ cordis minimæ*), which return a small quantity of blood directly from the substance of the heart.

The *right atrioventricular orifice* is the large opening between the right atrium and ventricle; it is described with the right ventricle (p. 583).

The *valve of the inferior vena cava* is situated in front of the orifice of the inferior vena cava. It is semilunar in form, its convex margin being attached to the anterior margin of the orifice; its concave margin, which is free, ends in two cornua, of which the left is continuous with the anterior edge of the limbus fossæ ovalis, while the right is lost on the wall of the atrium. The valve is formed by a duplicature of the lining membrane of the atrium, containing a few muscular fibres. During fœtal life this valve is of large size, and serves to direct the blood from the inferior vena cava into the left atrium through an opening, named the foramen ovale, in the atrial septum. It occasionally persists in the adult, and may assist in preventing the return of blood into the inferior vena cava; it may present a cribriform or filamentous appearance; sometimes it is absent.

The *valve of the coronary sinus* (fig. 639) is a semicircular fold of the lining membrane of the atrium, at the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the atrium. This valve may be double or it may be cribriform.

The *fossa ovalis* (fig. 639) is an oval depression on the lower part of the septal wall of the atrium, above and to the left of the orifice of the inferior vena cava. It corresponds to the situation of the foramen ovale in the fœtus.

FIG. 640.—A transverse section through the ventricles of the heart.

The *limbus fossæ ovalis* (annulus ovalis) (fig. 639) is the prominent margin of the fossa ovalis. It is most distinct above and at the sides of the fossa; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa, leading upwards, beneath the limbus, into the left atrium; it is the remnant of the foramen ovale between the two atria.

The *intervenous tubercle* (tubercle of Lower) is a small projection on the posterior wall of the right atrium, above the fossa ovalis. It is distinct in the hearts of quadrupeds, but in man is scarcely visible. During fœtal life it may direct the blood from the superior vena cava towards the atrioventricular opening.

The *crista terminalis* and the *musculi pectinati* have been described (p. 581).

The **right ventricle** (figs. 639, 640, 642) extends from the right atrium to the apex of the heart. Its anterosuperior surface is convex, and forms

connects the posterior
e of the conus
osus to the aorta;
tendon is continuous
the membranous
ricular septum. The
of the right ventricle is thinner than that of the left, the proportion
en them being as 1 to 3; it is thickest at the base, and gradually
mes thinner towards the apex of the ventricle. The cavity of the right
cle is capable of holding about 85 c.c. of blood.

The interior of the right ventricle (fig. 639) presents the following parts
examination:

Orifices { Right atrioventricular. Pulmonary artery.	Valves { Tricuspid. Pulmonary.
Trabeculæ carneæ.	Chordæ tendineæ.

The *right atrioventricular orifice* is the large oval aperture between the right
m and ventricle. Situated at the base of the ventricle, it measures about
in diameter and is encircled by a fibrous ring, covered with the lining
brane of the heart; it is considerably larger than the left atrioventricular
e, being sufficient to admit the tips of four fingers. It is guarded by the
spid valve.

The *orifice of the pulmonary artery* is circular in form, and situated at the
nt of the conus arteriosus, close to the ventricular septum. It is placed
e and to the left of the atrioventricular opening, and is guarded by the
nary semilunar valves.

The *tricuspid valve* (figs. 639, 643) guards the right atrioventricular orifice,
consists of three somewhat triangular cusps or segments, *anterior*, *posterior*
medial; in the angles between the cusps small intermediate segments are
times seen. The anterior cusp, the largest, is interposed between the
ventricular orifice and the conus arteriosus, while the medial cusp is in
with the ventricular septum. Each cusp is formed by a duplicature of
ning membrane of the heart, strengthened by intervening layers of fibrous
. The central parts of the cusps are comparatively thick and strong,
marginal portions thin and translucent. Their bases are attached to the
s ring surrounding the atrioventricular orifice and are also joined to
other so as to form a continuous annular membrane, while their apices
into the ventricular cavity. Their atrial surfaces, directed towards
blood-current from the atrium, are smooth; their ventricular surfaces,
ed towards the wall of the ventricle, are rough and irregular and, together

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

with the apices and margins of the cusps, give attachment to a number of delicate tendinous cords, the *chordæ tendineæ*.

The *trabeculæ carneæ* are round or irregular muscular columns which rise from the whole of the inner surface of the ventricle, with the exception of the conus arteriosus, the wall of which is smooth. They are of three kinds: some are mere ridges, others are fixed at their ends but free in their middle, while a third set (*musculi papillares*) are continuous by their bases with the wall of the ventricle, while their apices project into the cavity, and give rise to the chordæ tendineæ which pass to be attached to the segments of the

FIG. 642.—A transverse section through the mediastinal cavity at the level of the body of the seventh thoracic vertebra.

tricuspid valve. There are two papillary muscles, anterior and posterior; the anterior is the larger, and its chordæ tendineæ are connected with the anterior and posterior cusps of the valve; the posterior papillary muscle sometimes consists of two or three parts, and its chordæ tendineæ are connected with the posterior and medial cusps. Some chordæ tendineæ also spring directly from the ventricular septum, or from small papillary eminences on it, and pass to the anterior and medial cusps. A muscular band, well marked in sheep and some other animals, frequently extends from the base of the anterior papillary muscle to the ventricular septum. From its attachment it may assist in preventing over-distension of the ventricle, and so has been named the *moderator band*.

The *pulmonary semilunar valves* (figs. 639, 641) are three in number, two in front and one behind, and are formed by duplicatures of the lining membrane strengthened by fibrous tissue. They are attached, by their convex margins

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the wall of the pulmonary artery at its junction with the ventricle, their borders being directed upwards into the lumen of the vessel. The free attached margins are strengthened by tendinous fibres, and at the middle the free margin there is a thickened nodule (*corpus Arantii*). From this are absent tendinous fibres radiate through the valve to its attached margin, on either side of the two narrow crescentic portions, the *lunulæ*, placed immediately adjoining the free margin (fig. 644). Opposite to the semilunar valves the pulmonary artery presents three slight dilatations or sinuses (sinuses of Valsalva).

Fig. 643.—The bases of the ventricles, exposed by removal of the atria.

The **left atrium** is rather smaller than the right, but its walls are thicker, measuring about 3 mm.; it consists, like the right, of two parts, a *principal cavity* and an *auricula*.

The *principal cavity* is cubical in form, and concealed, in front, by the pulmonary artery and aorta. It is separated from the right atrium by the atrial septum, and opening into it on either side are the two pulmonary veins.

The *auricula* is somewhat constricted at its junction with the principal cavity; it is longer, narrower, and more curved than that of the right atrium, and its margins are more deeply indented. It is directed forwards on the left side of the pulmonary artery, and overlaps the root of this vessel.

The interior of the left atrium (fig. 645) presents the following parts for examination:

Orifices of the four pulmonary veins.
Left atrioventricular orifice.
Foramina venarum minimarum.
Musculi pectinati.

The *pulmonary veins*, four in number, open into the upper part of the posterior surface of the left atrium—two on either side of its middle line; their orifices are not provided with valves. The two left veins frequently end by a common opening.

The *left atrioventricular orifice* is the aperture between the left atrium and ventricle; it is described on p. 586.

The *foramina venarum minimarum* are the orifices of minute veins (venæ cordis minimæ) which return a small quantity of blood directly from the muscular substance of the heart.

The *musculi pectinati*, fewer and smaller than those in the right atrium, are confined to the inner surface of the auricula.

On the atrial septum may be seen a lunate impression, bounded below by a crescentic ridge, the concavity of which is directed upwards. The depression is just above the fossa ovalis of the right atrium.

The **left ventricle** is longer and more conical in shape than the right, and in transverse section its cavity presents an oval or nearly circular outline (fig. 640). It forms a small part of the sternocostal, and a considerable part of the diaphragmatic, surface of the heart; it also forms the apex of the heart. Its walls are about three times as thick as those of the right ventricle.

Its interior (fig. 645) presents the following parts for examination:

Orifices { Left atrioventricular. Aortic.
Trabeculæ carneæ.
Valves { Bicuspid or mitral. Aortic.
Chordæ tendineæ.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

The *left atrioventricular orifice* is placed below and to the left of the orifice. It is a little smaller than the right atrioventricular orifice, and the tips of only three fingers. It is surrounded by a dense fibrous ring is guarded by the bicuspid or mitral valve.

The *aortic orifice* is a circular aperture in front and to the right of atrioventricular orifice, from which it is separated by the anterior cusp of bicuspid valve. Its orifice is guarded by the aortic semilunar valves portion of the ventricle immediately below the aortic orifice is termed the *vestibule*, and possesses fibrous instead of muscular walls.

FIG. 644.—A transverse section through the mediastinal cavity at the level of the lower part of the body of the sixth thoracic vertebra.

The *bicuspid or mitral valve* (figs. 643, 645) is attached to the fibrous which encircles the left atrioventricular orifice in the same way as tricuspid valve is attached around the right atrioventricular orifice. It consists of two triangular cusps, formed by duplicatures of the lining membrane strengthened by fibrous tissue, and containing a few muscular fibres. The cusps are of unequal size, and are larger, thicker, and stronger than those the tricuspid valve. The larger cusp is placed in front and to the right between the atrioventricular and aortic orifices, and is known as the *anterior or aortic cusp*; the smaller or *posterior cusp* is placed behind and to the left of the opening. Two small cusps are usually found in the angles between the larger cusps. The cusps of the bicuspid valve are furnished with chordæ tendineæ, which are attached in a manner similar to those on the right side the heart; they are, however, thicker, stronger, and less numerous.

The *aortic semilunar valves* (figs. 643, 646) are three in number, and surround the orifice of the aorta; two are posterior (right and left), and one anterior

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are similar in structure, and in their mode of attachment, to the monary semilunar valves, but are larger, thicker, and stronger; the lunulæ more distinct, and the noduli or corpora Arantii thicker and more pro-. Opposite the valves the aorta presents slight dilatations, the *aortic* (sinuses of Valsalva), which are larger than those at the origin of the monary artery.

The *trabeculæ carneæ* are of three kinds, like those in the right ventricle, but are more numerous, and present a dense interlacement, especially at the and upon the posterior wall, of the ventricle. The *musculi papillares* two in number, one springing from the anterior, the other from the posterior they are of large size, and end in rounded extremities from which the tendineæ arise. Chordæ tendineæ from each papillary muscle are nected to both cusps of the bicuspid valve.

FIG. 645.—The interior of the left side of the heart.

structure.—The heart consists of muscular fibres (*myocardium*), and of fibrous which partly serve for their attachment. It is covered with the visceral of the serous pericardium (*epicardium*), and lined with the *endocardium*.

The *endocardium* is a thin, smooth, glistening membrane which lines the bers of the heart, and is continuous with the lining membrane of the large d-vessels; by its reduplications it assists in forming the valves. It consists layer of endothelial cells placed on a stratum of connective tissue and elastic

The *fibrous rings* surround the atrioventricular and arterial orifices, and are ger on the left than on the right side of the heart. The atrioventricular rings e for the attachment of the muscular fibres of the atria and ventricles, and the attachment of the bicuspid and tricuspid valves. The left atrioventricular is closely connected, by its anterior margin, with the aortic arterial ring; en these and the right atrioventricular ring is a triangular mass of fibrous , the *trigonum fibrosum*, which represents the *os cordis* of some of the larger als, as the ox and elephant. There is also the tendon of the conus arteriosus, ly referred to (p. 583).

The fibrous rings surrounding the arterial orifices serve for the attachment of great vessels and the semilunar valves. Each ring receives, by its ventricular

margin, the attachment of some of the muscular fibres of the ventricles; its o margin presents three deep semicircular notches, to which the middle coat artery is firmly fixed. The attachment of an artery to its fibrous ring is strengt by the external coat of the artery and the epicardium externally, and endocardium internally. From the margins of the semicircular notches, the structure of the continued into ments of the valves middle coat of the in this situation and the vessel is to form the sinus the aorta and pul artery.

FIG. 646.—The aorta laid open to show the semilunar valves.

The *muscular* of the heart con fibres, which are versely and longitu striated (p. 33), and sent an exceedingly cate interlacement. comprise (*a*) the fib the atria, (*b*) the of the ventricles, (*c*) the atrioventr bundle.

The *fibres of the atria* are arranged in two layers—a superficial, common to atria, and a deep, proper to each. The *superficial fibres* are most distinct o front of the atria, across the bases of which they run in a transverse dire forming a thin and incomplete layer; some of them pass into the atrial se The *deep fibres* consist of looped and annular fibres. The *looped fibres* pass up over each atrium, and are attached by their extremities to the correspo atrioventricular ring, in front and behind; the *annular fibres* surround the aur and form annular bands around the terminations of the veins and around fossa ovalis.

The *fibres of the ventricles* are arranged in a complex manner, and various acco have been given of their course and connexions; the following description is ba on that given by MacCallum.* They consist of superficial and deep layers, all of which, with the exception of two, are inserted into the papillary muscles of the ventricles. The *superficial layers* comprise the following: (*a*) Fibres which spring from the tendon of the conus arteriosus (p. 583) and sweep downwards and towards the left across the anterior longitudinal sulcus and around the apex of the heart, where they form a vortex (fig. 647) and pass upwards and inwards to terminate in the papillary muscles of the left ventricle; those arising from the upper half of the tendon of the conus arteriosus pass to the anterior papillary muscle, those from the lower half to the posterior papillary muscle and papillary muscles of the septum (fig. 648). (*b*) Fibres which arise from the right a ventricular ring and run diagonally across the diaphragmatic surface of the r ventricle and round its right border on to its sternocostal surface, where they

...6. 649.—A diagram of the course of the ...ngest layer of muscular fibres of the ...ft ventricle. (After MacCallum.)

The *atrioventricular bundle* (fig. 650) is a direct muscular connexion between the atria and the ventricles. It arises in association with two small collections of spindle-shaped cells, the sino-atrial and atrioventricular nodes. The *sino-atrial node* is situated on the right border of the opening of the superior vena cava in the upper part of the sulcus terminalis; from it strands of fusiform fibres run under the endocardium of the wall of the right atrium to the *atrioventricular node* which lies near the orifice ...the coronary sinus in the annular and septal fibres of the right atrium. From ...atrioventricular node the atrioventricular bundle passes forwards below the ...branous septum, and divides into right and left fasciculi. These run down in

* Franklin P. Mall gives an account of his researches 'On the muscular architecture of the ...ventricles of the human heart' in the *American Journal of Anatomy*, vols. 11 and 13.

Digitized by Arya Samaj Foundation Chennai and eGangotri

the right and left ventricles, one on either side of the ventricular septum, e with endocardium. The right fasciculus passes into the moderator band breaks up into numerous strands which end in an intricate network on the pa muscles and on the wall of the right ventricle. The left fasciculus consists of main strands, an anterior and a posterior, which are distributed to the papillary muscles and the wall of the left ventricle. The atrioventricular bundle divisions are enveloped in a sheath of connective tissue; by injecting this with Indian ink the ramifications of the bundle can be demonstrated. The and greater portion of the bundle consists of narrow, somewhat fusiform fibres the terminal strands of the bundle are composed of Purkinje fibres.

FIG. 650.—A schematic representation of the atrioventricular bundle. The course of the bundle is represented in red.

E. A. S.

Kent has described a second atrioventricular bundle in the right lateral of the heart, containing cardiac muscle-fibres, fine nerve-fibres, and fibres resem those of Purkinje. This bundle is connected with a node in the wall of the atrium, formed of fine, faintly striated muscle-fibres.

A. Morison * has shown that in the sheep and pig the atrioventricular b 'is a great avenue for the transmission of nerves from the auricular to ventricular heart'; large and numerous nerve-trunks enter the bundle and with it. Branches arise from these nerve-trunks and form plexuses around of Purkinje cells, and from these plexuses fine fibrils go to innervate individual

The sino-atrial and atrioventricular nodes, the atrioventricular bundle and its fasciculus, are supplied by the right coronary artery; the left fasciculus of the bun supplied by both coronary arteries.

Applied Anatomy.—Clinical and experimental evidence go to prove that this bundle ...ves the impulse to systolic contraction from the atrial septum to the ventricles, and ...h attention has been paid to it, because it appears to become fibrosed and to lose much ...conducting power (heart-block) in many cases of Adams-Stokes' syndrome. This ...tion is characterised by a slow pulse, a tendency to syncopal or epileptiform seizures, ...the fact that while the cardiac atria beat at a normal rate, the ventricles contract ...h less frequently.

Vessels and Nerves.—The *arteries* supplying the heart are the right and left ...nary branches of the aorta (p. 598); the majority of the *veins* are drained by ...coronary sinus into the right atrium.

The *lymphatic* vessels are described on p. 778.

The *nerves* are derived from the cardiac plexus (p. 978), which is formed by ...ches from the vagi and sympathetic. They are freely distributed both on the ...rdiac and in the substance of the heart, the separate nerve-filaments being furnished ...h small ganglia. The atrioventricular bundle receives nerve-fibres from ganglia ...the atrial septum. Other ganglia are found in relation with the sino-atrial ...le, and supply it with nerve-filaments.

The cardiac cycle and the actions of the valves.—By the contractions of the ...r the blood is pumped through the arteries to all parts of the body. These ...ractions occur regularly and at the rate of about seventy per minute. Each ...e of contraction or *period of activity* is followed by a *period of rest*, the two ...ods constituting what is known as a *cardiac cycle*.

Each cardiac cycle consists of three phases, which succeed each other as follows: ...a short simultaneous contraction of both atria, termed the *atrial systole*, followed, ...r a slight pause, by (2) a simultaneous, but more prolonged, contraction of ...h ventricles, named the *ventricular systole*, and (3) a *period of rest*, during which ...e whole heart is relaxed. The atrial contraction commences around the venous ...ings, and sweeping over the atria forces their contents through the atrio-...ntricular openings into the ventricles, regurgitation into the veins being prevented ...the contraction of their muscular coats. When the ventricles contract, the ...spid and bicuspid valves are closed, and prevent the passage of the blood ...k into the atria; the musculi papillares at the same time are shortened, and, ...ing on the chordæ tendineæ, prevent the inversion of the valves into the atria. ...soon as the pressure in the ventricles exceeds that in the pulmonary artery ...l aorta, the valves guarding the orifices of these vessels are opened, and the ...d is driven from the right ventricle into the pulmonary artery, and from the left ...the aorta. The moment the systole of the ventricles ceases, the pressure ...the blood in the pulmonary artery and aorta closes the pulmonary and aortic ...lunar valves, thus preventing regurgitation of blood into the ventricles, and ...valves remain shut until re-opened by the next ventricular systole. During ...period of rest the tension of the tricuspid and bicuspid valves is relaxed, and ...d flows from the veins through the atria into the ventricles. The filling of ...ventricles is completed by the systole of the atria. The average duration ...a cardiac cycle is about $\frac{8}{10}$ of a second, made up as follows:

Atrial systole, $\frac{1}{10}$.	Atrial diastole, $\frac{7}{10}$.
Ventricular systole, $\frac{3}{10}$.	Ventricular diastole, $\frac{5}{10}$.
Total systole, $\frac{4}{10}$.	Complete diastole, $\frac{4}{10}$.

The rhythmical action of the heart is *muscular* in origin—that is to say, the ...t-muscle possesses the inherent property of contraction apart from any ...vous stimulation. The more embryonic the muscle the better is it able to ...te the contraction wave, and the normal systole of the heart starts at the ...-atrial node, where the muscle is most embryonic in nature: for this reason ...e sino-atrial node has been called the "pace-maker" of the heart. A slight ...e occurs between systole of the atria and that of the ventricles. This is due ...the fact that the contraction of the ventricles is excited by an impulse conveyed ...the atrioventricular bundle, conduction along the fibres of which is relatively ...w. The nerves, although not concerned in originating the contractions of the ...t-muscle, play an important rôle in regulating their force and frequency in ...der to subserve the physiological needs of the organism.

Applied Anatomy.—Wounds of the heart are often immediately fatal, but not neces-...ily so. They may be non-penetrating, when death may occur from hæmorrhage if one ...the coronary vessels has been wounded, or subsequently from pericarditis. Even a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

penetrating wound is not necessarily fatal, as many cases have been recorded in which the wound has been sutured successfully. When blood is effused into the pericardium it presses especially on the thin-walled atria, and so interferes with the circulation through the heart.

The Chief Peculiarities in the Vascular System of the Fœtus

The development of the heart and vascular system is described on pp. 131 to 132.

The chief peculiarities of the fœtal heart are the communication between the atria through the foramen ovale, and the large size of the valve of the inferior vena cava. The following points may also be noted: (1) In early fœtal life the heart lies immediately below the mandibular arch, and as development proceeds it is gradually drawn within the thorax. (2) For a time the atrial portion exceeds the ventricular in size, and the walls of the ventricles are of equal thickness, since each ventricle bears the pressure of the systemic circulation. Towards the end of fœtal life the ventricular portion becomes larger, and the wall of the left ventricle exceeds that of the right in thickness, thus becoming adapted to bear the pressure of the whole systemic circulation. (3) Its size is large as compared with that of the rest of the body, the proportion at the second month of fœtal life being 1 to 50; at birth 1 to 120; in the adult about 1 to 160.

The *foramen ovale* is an opening between the atria until the end of fœtal life; it is obliterated shortly after birth (p. 115).

The *valve of the inferior vena cava* directs the blood from the inferior vena cava through the foramen ovale into the left atrium.

The chief peculiarities in the arterial system of the fœtus are (1) the communication between the pulmonary artery and the aorta by means of the ductus arteriosus, and (2) the continuation of the hypogastric arteries as the umbilical arteries to the placenta.

The *ductus arteriosus* is a short tube, about 1 cm. in length at birth, and of the diameter of a goose-quill. In early fœtal life it forms the continuation of the pulmonary artery, and opens into the aorta, just beyond the origin of the left subclavian artery; and so conducts a great part of the blood from the right ventricle into the aorta. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery. It is obliterated within a few days after birth.

In the fœtus the *hypogastric arteries* are continued along the sides of the urinary bladder, thence upwards on the back of the anterior abdominal wall to the umbilicus, through which they pass out of the abdomen and run, under the name of the *umbilical arteries*, in the umbilical cord to the placenta. They convey blood from the fœtus to the placenta.

The chief peculiarities in the venous system of the fœtus are the communications established between the placenta and the liver and portal vein through the umbilical vein; and between the umbilical vein and the inferior vena cava through the ductus venosus.

The Fœtal Circulation (fig. 651)

The fœtal blood is carried to the placenta by the umbilical arteries and returned from the placenta to the fœtus by the two umbilical veins. These veins unite in the umbilical cord to form a single vein (vena umbilicalis impar) which divides within the embryo into a right and a left umbilical vein. After the formation of the liver the right umbilical vein atrophies and disappears, but the left persists until the end of fœtal life. It enters the abdomen at the umbilicus, and passes along the free margin of the falciform ligament of the liver, to the visceral surface of that organ, where it gives off two or three branches, one of large size to the left lobe, and others to the lobus quadratus and lobus caudatus. At the porta hepatis (transverse fissure of the liver) it divides into two branches; of these, the larger is joined

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the portal vein, and enters the right lobe; the smaller is continued upwards under the name of the ductus venosus, and joins the inferior vena cava. The blood conveyed by the left umbilical vein passes to the inferior vena cava in

FIG. 651.—A plan of the fœtal circulation.

In this plan the arrows represent the course which the blood takes in the heart and vessels.

the different ways. Some enters the liver directly and is carried to the inferior vena cava by the hepatic veins; a considerable quantity circulates through the liver with the portal venous blood, before entering the inferior vena cava by the hepatic veins; the remainder passes directly into the inferior vena cava through the ductus venosus.

In the inferior vena cava, the blood carried by the ductus venosus and hepatic veins mixes with that returning from the lower extremities and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

abdominal wall. It enters the right atrium, and, guided by the valve of the inferior vena cava, passes through the foramen ovale into the left atrium, where it mingles with a small quantity of blood returned from the lungs by the pulmonary veins. From the left atrium it passes into the left ventricle, and from that cavity into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. The blood from the head and upper extremities is returned by the superior vena cava to the right atrium, where it mixes with a small portion of that returned by the inferior vena cava. From the right atrium the blood passes into the right ventricle, and thence into the pulmonary artery. The lungs of the fœtus being inactive, only a small quantity of the blood conveyed by the pulmonary artery is distributed to them by the right and left pulmonary arteries, and returned by the pulmonary veins to the left atrium: the greater part passes through the ductus arteriosus into the aorta, where it mixes with the small quantity of blood transmitted by the left ventricle into this part of the aorta. It descends through the aorta, is in part distributed to the lower extremities and the viscera of the abdomen and pelvis, but most of it is conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fœtus the following facts will be inferred: 1. The placenta serves the purposes of nutrition and excretion, receiving the impure blood from the fœtus, and returning it purified and charged with nutritive material. 2. A large part of the blood of the left umbilical vein traverses the liver before entering the inferior vena cava; this is correlated with the relatively large size of the liver, especially at an early period of fœtal life. 3. The right atrium is the place of meeting of a double current, the blood from the inferior vena cava being guided by the valve of this vessel through the foramen ovale into the left atrium, while that in the superior vena cava descends into the right ventricle. At an early period of fœtal life it is highly probable that the two streams are quite distinct, for the inferior vena cava opens almost directly into the left atrium, and the valve of the inferior vena cava would exclude the current from the right ventricle. At a later period, as the separation between the two streams becomes more marked, it seems probable that some mixture of the two streams must take place. 4. The pure blood carried from the placenta to the fœtus, mixed with the blood from the portal vein and inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities. 5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and limbs, together with a small quantity from the right ventricle, is distributed to the abdomen and lower extremities.

The Changes in the Vascular System at Birth

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, and the placental circulation is cut off. The foramen ovale is closed by the septum secundum (p. 1[illegible]) about the tenth day after birth; sometimes a slit-like opening is left between the two atria.

The *ductus arteriosus* begins to contract immediately after respiration is established, and is completely closed between the fourth and fifth days after birth; it ultimately forms an impervious cord, the *ligamentum arteriosum*, which connects the left pulmonary artery to the arch of the aorta.

The parts of the *hypogastric arteries* extending from the sides of the bladder to the umbilicus become obliterated between the second and fifth days after birth, and project towards the abdominal cavity as fibrous cords; these cords are termed the lateral umbilical ligaments, and are enveloped by folds of peritoneum.

The *left umbilical vein* and the *ductus venosus* are completely obliterated between the second and fifth days after birth; the former becomes the ligamentum teres, the latter the ligamentum venosum, of the liver.

THE ARTERIES

The distribution of the systemic arteries is like a highly branched tree, the common trunk of which, formed by the aorta, commences at the left ventricle, while the smallest ramifications extend to the viscera and to the peripheral parts of the body. Arteries are found in all parts of the body, except in the hairs, nails, epidermis, cartilages, and corneæ; the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor surfaces, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as in the cœliac artery and the thyreocervical trunk; more usually the vessel gives off several branches in succession, and still continues as the main trunk, as in the arteries of the limbs.

A branch of an artery is smaller than the trunk from which it arises; but when an artery divides into two branches, the combined sectional area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined sectional area of all the arterial branches greatly exceeds that of the aorta.

The arteries unite with one another, forming what are called *anastomoses*. Anastomosis between trunks of nearly equal size is found in the brain, where the two vertebral arteries unite to form the basilar artery, and the two anterior cerebral arteries are connected by the anterior communicating artery; and in the abdomen, where the intestinal arteries have free anastomoses between their larger branches. In the limbs, the anastomoses are largest and most numerous around the joints; the branches arising from an artery above a joint uniting with branches from the vessels below it. These anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a *collateral circulation* is established after the application of a ligature to a main artery. The smaller branches of arteries anastomose more frequently than the larger; and between the smallest twigs these anastomoses may be so numerous that they constitute a close network. In certain regions of the body, however, there are arteries which have no anastomoses with neighbouring arteries except through the agency of the capillaries. Such are found in the spleen and kidney, and in certain parts of the brain, and are called *end arteries*. If an artery of this type be occluded, serious nutritional disturbances resulting in death (necrosis) will occur in the terrtiory supplied by the vessel.

Applied Anatomy.—The walls of all the arteries, and most of all of the aorta, are liable to various forms of hardening with loss of elasticity, known collectively as *arteriosclerosis*, and are of the greatest clinical importance. The two chief varieties of arteriosclerosis are: (1) hypertrophy of the muscular tunica media of the arteries, clinically associated with chronic arterial vasoconstriction and high blood-pressure, and (2) atheroma or atherosclerosis, essentially a senile degenerative change of the intima, that leads to loss of arterial elasticity by the replacement of elastic by fibrous tissue. Whatever the cause of arterial sclerosis its chief ill-effects on the patient are two. In the first place, it is associated with a permanent and often considerable rise in the arterial blood-pressure, involving a corresponding hypertrophy of the heart; in the second, it weakens the vessel walls, tendering them more liable to rupture, while at the same time it is apt to lessen the calibre of the affected vessels.

The arteries are also frequently attacked by syphilis, which gives rise to inflammation and degeneration of their middle coats. Arterial aneurysms, other than those due to direct injury, occur almost solely in syphilitic patients.

The Pulmonary Artery

The **pulmonary artery** (figs. 652, 653) conveys venous blood from the right ventricle of the heart to the lungs. It is about 5 cm. in length and 3 cm. in diameter, and arises from the conus arteriosus of the right ventricle. It runs upwards and backwards, passing at first in front and then to the left of the ascending aorta, as far as the under surface of the aortic arch, where it divides, at the level of the fibrocartilage between the fifth and sixth thoracic vertebræ, into the right and left branches of nearly equal size.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Relations.—The whole of the pulmonary artery is contained within the cardium. It and the ascending aorta are enclosed in a common tube of visceral layer of the serous pericardium. The fibrous layer of the pericardium gradually lost upon the external coats of the two branches of the artery. In the the pulmonary artery is separated from the anterior end of the second left intercostal space by the pleura, the left lung, and the pericardium; it lies first upon the ascending aorta; higher up it lies in front of the left atrium; the ascending aorta is on its right side. On either side of its origin is auricula of the corresponding atrium, and a coronary artery; the left coronary artery, in the first part of its course passes behind the vessel. The superior part of the cardiac plexus lies between the division of the pulmonary artery the arch of the aorta.

Fig. 652.—A transverse section through the thorax, showing the relations of the pulmonary artery, etc. Diagrammatic.

The **right branch** of the pulmonary artery, slightly longer and larger than the left, runs horizontally to the right, behind the ascending aorta, superior vena cava, and upper right pulmonary vein, and in front of the right bronchus to the root of the right lung, where it divides into two branches. The lower and larger of these is distributed to the middle and lower lobes of the lung; the upper and smaller accompanies the eparterial bronchus to the upper lobe.

The **left branch** of the pulmonary artery, a little shorter and smaller than the right, runs horizontally in front of the descending aorta and the bronchus to the root of the left lung, where it divides into two branches, one for either lobe of the lung. Above, it is united to the concavity of the aortic arch by the ligamentum arteriosum, on the left of which is the left recurrent nerve, and on the right the superficial part of the cardiac plexus. Below it is joined to the upper left pulmonary vein by the ligament of the left vena cava (p. 576).

The terminal branches of the pulmonary arteries are described with the anatomy of the lungs.

Applied Anatomy.—Stenosis (narrowing) or atresia (non-perforation) of the pulmonary orifice, usually combined with other developmental anomalies such as defect of the upper part of the interventricular septum, patency of the ductus arteriosus, or patency of

...ovale, is the commonest form of congenital heart disease. It is due to mal-...opment, and not to fœtal endocarditis; possibly, as Keith suggests, to malformation ...the bulbus cordis. In well-marked cases the child with congenital heart disease is ...cyanosed, short of breath on exertion, and puny, generally dying of sudden heart failure ...endocarditis before adolescence. The chief signs of the condition are the loud, harsh ...cardiac murmur best heard over the second left costal cartilage, cyanosis, club-...of the finger-tips, and the presence of an excess of red corpuscles in the blood.

Embolism of the pulmonary artery by a clot of blood coming from the right side of ...heart in patients with heart-disease, or from a thrombosed vein in cases, for example, ...influenza, enteric fever, puerperal sepsis, or fractured limbs, is a common cause of ...sudden or rapid death. The patient may cry out with sudden excruciating pain in the ...chest when the detached embolus lodges, and after a brief period of intense dyspnœa, ...cyanosis, and anguish, die.

The Aorta

The **aorta** is the main trunk of the series of vessels which convey the ...oxygenated blood to the tissues of the body. It begins at the upper part of ...the left ventricle, where it is about 3 cm. in diameter, and after ascending for

Fig. 653.—A transverse section through the mediastinal cavity at the level of the upper part of the body of the sixth thoracic vertebra.

...short distance, arches backwards and to the left, over the root of the left ...lung; it then descends within the thorax on the left side of the vertebral column, ...and enters the abdominal cavity through the aortic hiatus in the Diaphragm. ...considerably diminished in size (about 1·75 cm. in diameter), it ends, on the ...left of the median plane, at the level of the lower border of the fourth lumbar ...vertebra, by dividing into the right and left common iliac arteries. Hence it is ...described in several portions, viz. the *ascending aorta*, the *arch of the aorta*, ...and the *descending aorta*, which last is divided into the *thoracic* and *abdominal*

The Ascending Aorta

The **ascending aorta** (figs. 635, 655) is about 5 cm. long. It l at the base of the left ventricle, on a level with the lower border of third costal cartilage, behind the left half of the sternum; it obliquely upwards, forwards, and to the right behind the sternum, direction of the heart's axis, as high as the upper border of the secon costal cartilage, describing a slight curve in its course. At its origin it p opposite the segments of the aortic valve, three small dilatations call aortic sinuses. At the union of the ascending aorta with the aortic a

Fig. 654.—A transverse section through the mediastinal cavity at the level of the lower part of the body of the fourth thoracic vertebra.

calibre of the vessel is slightly increased, owing to a bulging of its right This dilatation is termed the *bulb of the aorta*, and on transverse section at level, the vessel presents a somewhat oval figure.

Relations.—The ascending aorta is contained within the pericardium, and enclosed in a tube of the serous pericardium, common to it and the pulm artery. It is covered at its commencement by the trunk of the pulmonary a and the right auricula, and, higher up, is separated from the sternum by pericardium, the right pleura, the anterior margin of the right lung, some areolar tissue, and the remains of the thymus; *posterior* to it are the left atri the right pulmonary artery, and the right bronchus. On its *right side* are superior vena cava and right atrium, the former lying partly behind it; on *left side* is the pulmonary artery.

Branches.—The branches of the ascending aorta are the right and left coro arteries (figs. 638, 655) which supply the heart; they arise from the aortic sin immediately above the attached margins of the aortic semilunar valves.

The **right coronary artery** arises from the anterior aortic sinus. It passes first between the conus arteriosus and the right auricle, turns round the right margin and then runs in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

of the coronary sulcus, coursing on the front of the heart from left to right, on the back of the heart from right to left as far as the posterior longi- sulcus; under the name of the *posterior descending branch* it proceeds down sulcus, sometimes as far as the apex of the heart. The right coronary artery a large *marginal branch* which follows the acute margin of the heart towards ex, and ramifies on both surfaces of the right ventricle. It also supplies ss to the right atrium and to the part of the left ventricle which adjoins posterior longitudinal sulcus.

FIG. 655.—The arch of the aorta, and its branches.

FIG. 656.—Plan of the branches.

The **left coronary artery**, larger than the right, arises from the left posterior sinus and, after a short forward course between the pulmonary artery and left auricula, divides into an anterior descending and a circumflex branch. *Anterior descending branch* runs forwards between the pulmonary artery and left auricula, and reaching the anterior longitudinal sulcus, descends in it to the fossa apicis cordis; it gives branches to both ventricles. In many subjects the anterior descending branch turns round the apex (fig. 638) and ascends for a varying distance in the posterior longitudinal sulcus. The *circumflex branch* follows the part of the coronary sulcus, running first to the left and then to the right, reaching nearly as far as the posterior longitudinal sulcus; it gives branches to the left atrium and ventricle.

There is a very free anastomosis between the minute branches and between capillaries of the two coronary arteries in the substance of the heart.*

Peculiarities.—The coronary arteries occasionally arise by a common trunk; number may be increased to three or four.

Applied Anatomy.—The sudden blocking of a coronary artery by an embolus, or more gradual obstruction by arterial disease or thrombosis, is a common cause of death in persons past middle age. If the obstruction to the passage of blood is complete, *angina pectoris* may occur. In this condition the patient is suddenly seized with spasm of agonising pain in the precordial region and down the left arm, together with an indescribable sense of anguish. He may die in such an attack, or succumb a few hours or days later from heart failure, or survive a number of attacks.

The Arch of the Aorta

The **arch of the aorta** (figs. 655, 657) connects the ascending with the descending aorta; it begins at the level of the upper border of the second sternocostal articulation, and runs at first upwards, backwards, and to the left in front of the trachea; it is then directed backwards on the left side of

Fig. 657.—A transverse section through the mediastinal cavity at the level of the upper part of the body of the fourth thoracic vertebra.

the trachea, and finally passes downwards on the left side of the body of the fourth thoracic vertebra, at the lower border of which it is continuous with the descending aorta. It thus forms two curvatures: one with its convexity upwards, the other with its convexity forwards and to the left. Its upper border is usually about 2·5 cm. below the superior border of the manubrium sterni.

Relations.—The arch of the aorta is covered *anteriorly* by the pleura, the anterior margins of the lungs, and by the remains of the thymus. As the vessel runs backwards its *left* side is in contact with the left lung and pleura. Its

wards on the left side of this part of the arch are four nerves, in order from backwards these are: the left phrenic, the lower of the superior cardiac ves of the left vagus, the superior cardiac branch of the left sympathetic, and nk of the left vagus. As the left vagus crosses the arch it gives off its recurrent which hooks round below the vessel and then passes upwards on its right The left superior intercostal vein runs obliquely upwards and forwards e left side of the arch, between the phrenic and vagus nerves. On the are the deep part of the cardiac plexus, the left recurrent nerve, and the agus; the trachea lies behind and to the right of the vessel. *Above* e innominate, left common carotid, and left subclavian arteries, which arise the convexity of the arch and are crossed close to their origins by the left minate vein. *Below* are the bifurcation of the pulmonary artery, the left chus, the ligamentum arteriosum, the superficial part of the cardiac plexus, e left recurrent nerve. As already stated (p. 596), the ligamentum arteriosum ks the commencement of the left pulmonary artery to the aortic arch.

In the fœtus the lumen of the aorta is considerably narrowed between the origin the left subclavian artery and the attachment of the ductus arteriosus, forming is termed the *aortic isthmus*, while immediately beyond the ductus arteriosus vessel presents a fusiform dilatation which His has named the *aortic spindle*—point of junction of the two parts being marked in the concavity of the arch indentation or angle. These conditions persist, to some extent, in the adult, e His found that the average diameter of the spindle exceeded that of the us by 3 mm.

Peculiarities.—The summit of the arch of the aorta is usually about 2·5 cm. below the r border of the sternum; but it may reach nearly to the top of the bone. Occasion- it is found 4 cm., more rarely from 5 to 8 cm., below this point. Sometimes the aorta s over the root of the right lung (right aortic arch) instead of over that of the left, passes down on the right side of the vertebral column, a condition which is normal s. In such cases there is a transposition of the thoracic and of the abdominal viscera. frequently the aorta, after arching over the root of the right lung, is directed to its position on the left side of the vertebral column; this peculiarity is not accompanied transposition of the viscera. The aorta occasionally divides, as in some quadrupeds, an ascending and a descending trunk, the former of which is directed vertically upwards, subdivides into three branches, to supply the head and upper extremities. Some- the aorta subdivides near its origin into two branches, which soon reunite; in one of this kind the œsophagus and trachea passed through the interval between the two ches; this is the normal condition of the vessel in the reptilia.

Applied Anatomy.—The ascending aorta and the arch of the aorta are frequent sites eurysm.

Aneurysm of the ascending aorta, in a majority of cases affects the anterior sinus, owing the fact that the regurgitation of blood which follows the closing of the aortic valves ected chiefly against the anterior wall of the vessel. If the aneurysmal sac projects rds it may destroy part of the sternum and the costal cartilages, usually on the right , and appear as a pulsating tumour on the front of the chest. In other cases it may press or open into the right lung, bronchi, or trachea; it may burst into the peri- rdium (a common cause of death in these aneurysms), or may compress the right atrium, pulmonary artery and the adjoining part of the right ventricle, and open into one or er of these structures. It may press upon the superior vena cava or the innominate s, causing great venous engorgement in their tributaries; an aneurysm has occasionally rated into the superior vena cava setting up an arteriovenous aneurysm.

Regarding the arch of the aorta, the student is reminded that the vessel lies against trachea, left bronchus, œsophagus, and thoracic duct; that the recurrent nerve winds und it; and that from its upper part are given off three large trunks, which supply head, neck, and upper extremities. An aneurysmal tumour taking origin from the erior part of the vessel, its most usual site, may press upon the trachea and give rise the sign known as 'tracheal tugging,' impede the breathing, or produce cough, ea, bronchiectasis, hæmoptysis, or stridulous breathing, or it may ultimately burst that tube, producing fatal hæmorrhage. Again, its pressure on the left recurrent may give rise to symptoms of laryngeal paralysis; or it may press upon the thoracic and destroy life by inanition; or it may involve the œsophagus, producing dysphagia, has not infrequently been mistaken for œsophageal stricture; or it may burst into phagus, when fatal hæmorrhage will occur. Pressure on the sympathetic filaments produce (1) dilatation of the pupil by stimulation, or later (2) contraction of the pupil bolition of the conducting power of the nerves, on the affected side. The pupillary ges have however been attributed to the alterations of the blood-pressure in the carotid y on the affected side—lowering of pressure leading to partial collapse of the tortuous ls of the iris and dilatation of the pupil, increase of pressure tending to straighten these vessels and diminish the pupillary aperture. Again, the innominate artery, or

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the subclavian, or left carotid, may be so obstructed by clots as to produce a or even a disappearance, of the pulse in one or the other wrist, or in the left temporal artery; or the tumour may present itself at or above the manubrium, either in the median line, or to the right of the sternum, and may simulate of one of the arteries of the neck.

Many of the physical signs of an aortic aneurysm may be simulated with fidelity by the preternatural pulsation or throbbing of a distended and elastic no true aneurysmal dilatation exists. This condition may be met with in with aortic reflux and greatly hypertrophied hearts, in patients who are of a hysterical temperament, and in cases of Graves's disease or of marked condition is known as dynamic dilatation of the aorta, and in no way threatens

Branches (figs. 655, 658).—Three branches are given off from the of the arch of the aorta, viz.: the innominate, the left common caro the left subclavian.

Peculiarities.—The branches may spring from the commencement of the arch part of the ascending aorta; or the distance between them at their origin increased or diminished, the most frequent change in this respect being the tion of the left carotid to the innominate artery.

The number of the primary branches may be reduced to one; more com are two, the left carotid arising from the innominate artery, or (more rarely) and subclavian arteries of the left side arising from a left innominate artery. number may be increased to four, through the right carotid and subclavian arising directly from the aorta; in most of these cases the right subclavian arises left end of the arch; in other cases it is the second or third branch given off. common variation in which there are four primary branches is that where the bral artery arises from the arch of the aorta between the left carotid and arteries. Lastly, the number of trunks may be increased to five or six; in these the external and internal carotid arteries arise separately, the common caro absent on one or both sides. In some few cases six branches have been found, condition is associated with the origin of both vertebral arteries from the arch.

When the aorta arches over to the right side, the three branches have an arra the reverse of what is usual: there is a left innominate artery, and the right ca right subclavian arise separately. In other cases, where the aorta takes its usual the two carotids may be joined in a common trunk, and the subclavians arise from the arch, the right subclavian generally arising from the left end of the arch.

Other arteries may spring from the arch of the aorta. Of these the most are the bronchial, one or both, and the thyreoidea ima; the internal mammary inferior thyreoid have been seen to arise from it.

The Innominate Artery (figs. 655, 658, 659)

The **innominate artery** (arteria anonyma) is the largest branch arch of the aorta, and is from 4 to 5 cm. in length. It arises from the con of the arch of the aorta, posterior to the centre of the manubrium ster passes obliquely upwards, backwards, and to the right to the level of the border of the right sternoclavicular articulation, where it divides into right common carotid and right subclavian arteries.

Relations.—*Anteriorly*, it is separated from the manubrium sterni by the hyoideus and Sternothyreoideus, the remains of the thymus, the left inno and right inferior thyreoid veins which cross its root, and sometimes the cardiac branches of the right vagus nerve. *Posterior* to it is the trachea, crosses obliquely. On the *right side* are the right innominate vein, the upper of the superior vena cava, and the pleura; and on the *left side*, the remains thymus, the origin of the left common carotid artery, the inferior thyreoid and at a higher level the trachea.

Branches.—The innominate artery is usually devoid of branches than its terminal ones, but occasionally the *thyreoidea ima* arises from it. sometimes it gives off a *thymic* or a *bronchial branch*.

The **thyreoidea ima**, small and inconstant, ascends in front of the tra to the lower part of the thyreoid gland, in which it ends. It occasionally from the aorta, or from the right common carotid, subclavian or internal ma arteries.

Peculiarities.—The innominate artery sometimes projects above the upper bo the manubrium sterni. It may divide above the level of the sternoclavicular joint

The skin is then dissected back, and the Platysma divided: the sternal end of the cleidomastoideus is now brought into view, and a director being passed beneath it close to its deep surface so as to avoid any small vessels, it is to be divided; in the clavicular origin is to be divided throughout the whole or greater part of the ment. By pressing aside any loose cellular tissue or vessels that may now appear Sternohyoideus and Sternothyreoideus muscles will be exposed, and must be carefully drawn The inferior thyreoid veins may come into view, and must be carefully drawn upwards or downwards, by means of a blunt hook, or tied with double ligatures divided. After tearing through a strong fibrocellular lamina, the right common carotid brought into view, and being traced downwards, the innominate artery is reached left innominate vein should now be depressed; the right innominate vein, the

FIG. 659.—A transverse section through the mediastinal cavity at the level of the body of the third thoracic vertebra.

jugular vein, and the vagus nerve drawn to the right side; and a curved aneurysm may then be passed around the vessel, close to its surface, and in a direction from upwards and medially; care being taken to avoid the right pleural sac, the trachea cardiac nerves. The ligature should be applied to the artery as high as possible, in to allow room between it and the aorta for the formation of the coagulum. The tance of avoiding the thyreoid plexus of veins during the primary steps of the operation and the pleural sac while including the vessel in the ligature, should be most carefully borne in mind. To give freer access to the innominate artery a portion of the manubrium sterni is sometimes removed.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the bility of the establishment of the collateral circulation after ligature of the innominate artery, by tying and dividing that artery. He then found that 'Even coarse injection impelled into the aorta, passed freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely.'* The branches which this circulation is carried on are numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides are available for the supply of blood to the right side of the head and neck; the anastomosis between the costocervical of the subclavian and the first aortic intercostal (see *infra* on the lateral circulation after obliteration of the thoracic aorta) brings the blood, by a direct course, into the right subclavian; the numerous connexions between the costal arteries and the branches of the axillary and internal mammary arteries supply of blood to the right arm, while the inferior epigastric from the external the by means of its anastomosis with the internal mammary, compensates for any defect in the vascularity of the wall of the chest.

THE ARTERIES OF THE HEAD AND NECK

he principal arteries of the head and neck are the two common carotids; ascend in the neck and each divides into two branches, viz. (1) the external rotid, supplying the exterior of the head, the face, and the greater part of neck; (2) the internal carotid, supplying to a great extent the parts within cranial and orbital cavities.

The Common Carotid Arteries

The common carotid arteries differ in length and in their mode of origin. e *right* artery begins at the bifurcation of the innominate artery behind the ternoclavicular joint and is confined to the neck. The *left* artery springs from highest part of the arch of the aorta immediately behind and to the left e innominate artery, and therefore consists of a thoracic and a cervical rtion.

e thoracic portion of the left common carotid artery (figs. 658, 659) ds from the arch of the aorta to the level of the left sternoclavicular joint, re it is continuous with the cervical portion.

Relations.—*In front*, it is separated from the manubrium sterni by the Sternohyoideus and Sternothyreoideus, the anterior portions of the left pleura and lung, left innominate vein, and the remains of the thymus; *behind* it are the left bclavian artery, the trachea, the œsophagus, the left recurrent nerve, and the oracic duct. To its *right side* below, is the innominate artery, and above, trachea, the inferior thyreoid veins, and the remains of the thymus; to its *left* are the left vagus and phrenic nerves, the left pleura and lung.

The cervical portions of the common carotid arteries resemble each other ely that one description will apply to both (figs. 660, 661). Each passes ly upwards, from behind the sternoclavicular articulation, to the level upper border of the thyreoid cartilage, where it divides into the external internal carotid arteries; behind the point of division there is a small ish brown, ductless gland, named the *glomus caroticum* (carotid body).

At the lower part of the neck the two arteries are separated from each other narrow interval which contains the trachea; but at the upper part, the roid gland, the larynx, and the pharynx project forwards between the two ks. The common carotid artery is contained in a sheath, which is derived the fascia colli (deep cervical fascia) and encloses also the internal jugular and vagus nerve, the vein lying lateral to the artery, and the nerve between artery and vein, on a plane posterior to both. In the sheath, each of these ctures has a separate fibrous investment.

Relations.—In the lower part of its course the common carotid artery is very y seated, there being *in front* of it the skin, superficial fascia, Platysma, deep ical fascia, Sternocleidomastoideus, Sternohyoideus, Sternothyreoideus, and hyoideus; in the upper part of its course it is more superficial, being covered r by the skin, the superficial fascia, Platysma, deep cervical fascia, and the al margin of the Sternocleidomastoideus. When the latter muscle is drawn wards, the artery is seen to be contained in the *carotid triangle* (p. 621); this of the artery is crossed obliquely, from its medial to its lateral side, by the cleidomastoid branch of the superior thyreoid artery. In front of or within sheath is the descending branch of the hypoglossal nerve, this branch being ed by the descendens cervicalis nerve which springs from the second and third al nerves and crosses the vessel obliquely. The superior thyreoid vein crosses artery near its termination, and the middle thyreoid vein a little below the of the cricoid cartilage: the anterior jugular vein crosses the artery just above clavicle, but is separated from it by the Sternohyoideus and Sternothyreoideus. ind, the artery is separated from the transverse processes of the cervical vertebræ the Longus colli and Longus capitis, the sympathetic trunk being interposed ween the artery and the muscles; the inferior thyreoid artery crosses behind er part of the vessel. *Medial* to it are the œsophagus, trachea, and thyreoid ind (which overlaps it), the inferior thyreoid artery and recurrent nerve being

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

interposed; higher up, the larynx and pharynx. *Lateral* to the artery internal jugular vein and vagus nerve.

At the lower part of the neck, the right recurrent nerve crosses oblique the artery; the right internal jugular vein diverges from the artery, b approaches and often overlaps the lower part of the artery. Below the

FIG. 660.—A superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.

the sixth cervical vertebra the left common carotid artery is in relation poste with the vertebral artery, the cervical part of the thoracic duct crossing betw the two vessels.

Peculiarities.—In about 12 per cent. of subjects the *right* common-carotid artery a above the level of the upper border of the sternoclavicular articulation. It may ar a separate branch from the arch of the aorta, or in conjunction with the left carotid. *left* common carotid artery varies in its origin more frequently than the right. In majority of abnormal cases it arises with the innominate artery; if that artery be a the two carotids arise usually by a single trunk. It is rarely joined with the left subcl except in cases of transposition of the aortic arch.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

division of the common carotid artery may occur at or about the level of the hyoid more rarely it occurs below the usual level, opposite the middle of the larynx, or upper border of the cricoid cartilage; one case is described by Morgagni, where the was only 4 cm. in length and divided at the root of the neck. Very rarely the artery in the neck without undergoing subdivision, either the external or the internal being wanting. In a few cases the artery has been found absent, the external internal carotid arteries arising directly from the arch of the aorta; this peculiarity on both sides in some instances, on one side only in others.

common carotid artery usually supplies no branch; but it may give origin to the the superior thyreoid or its laryngeal branch, the ascending pharyngeal, the thyreoid, or the occipital.

Anatomy.—Aneurysms are not often found on the common carotid artery; they do occur they are usually situated low down at the root of the neck, or just the point of bifurcation of the vessel. They do not often assume a large size, and commonly found on the right side. As they increase in size they displace the and larynx, and therefore dyspnœa becomes a prominent symptom. Dysphagia

FIG. 661.—A transverse section through the anterior part of the neck at the level of the body of the first thoracic vertebra.

may be present from pressure on the œsophagus, especially if the aneurysm is on the side; and pressure on the recurrent nerve may produce hoarseness and laryngeal . Pressure on the sympathetic will cause pupillary changes—dilatation of the pupil the sympathetic is irritated or the arterial blood-supply to the eye is lessened, con- when the sympathetic has become paralysed; sympathetic irritation may also unilateral sweating of the head and neck. Pressure on the superficial branches of vical plexus may give rise to pain in the head, face and neck; pressure on the vagus gular action of the heart and to asthmatic attacks. It is important to bear in mind an enlarged lymph-gland in the superior carotid triangle, receiving a transmitted from the carotid artery, may simulate aneurysm of that vessel, but may be ished from it by the character of the pulsation, which is not expansile.

bolism of the left common carotid artery, or the thrombosis that may follow injury the wall of the vessel by penetrating gunshot wounds of the neck, have been known duce aphasia by interference with the blood-supply of the brain.

gital compression of the common carotid artery is sometimes required, and is best ed by pressing the vessel with the thumb against the anterior tubercle of the trans- process of the sixth cervical vertebra (p. 167).

the upper part of the common carotid artery should be selected as the spot upon which e a ligature (fig. 662 C), for the lower part is placed very deeply; moreover, on the s, the internal jugular vein, in most cases, passes obliquely in front of it. The part vessel which is most favourable for the operation is that opposite the level of the d cartilage. It occasionally happens that the artery divides below its usual position: artery be exposed at its point of bifurcation, both divisions of the vessel should be ear their origin, in preference to tying the trunk of the artery near its termination; d, in consequence of the entire absence of the common carotid artery, or from its division, two arteries, the external and internal carotids, are met with, the ligature ld be placed on that vessel which is found on compression to be connected with the ased area.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In this operation, the direction of the vessel and the anterior margin of the cleidomastoideus are the chief guides to its performance. The patient should be on his back with the head extended and turned slightly to the opposite side; an is to be made, 7 or 8 cm. long, in the direction of the anterior border of the Ster mastoideus, so that the centre corresponds to the level of the cricoid cartilage; dividing the integument, superficial fascia, Platysma, and deep fascia, the margins wound are held asunder by retractors, and the ramus descendens hypoglossi exposed must be avoided. The sheath of the vessel is to be raised by forceps, and opened small extent over the artery at its medial side. The internal jugular vein must itself alternately distended and relaxed, and must be carefully avoided. The needle is passed from the lateral aspect, care being taken to keep the needle contact with the artery, and thus avoid the risk of injuring the internal jugular including the vagus nerve. Before the ligature is tied, it should be ascertained nothing but the artery is included in it.

Fig. 662.—Dissections to show (A) the accessory nerve, (B) the lingual artery, (C) the common carotid artery, and (D) the third part of the subclavian artery.

Ligature of the common carotid near the root of the neck is sometimes required in cases of aneurysm of the upper part of the artery, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sternocleidomastoideus, which may be done in some cases, if the aneurysm is not of very large size, by an incision along the anterior border of the muscle, extending down to the sternoclavicular articulation, and by then retracting the muscle. Beneath it are two additional muscular layers, viz., the Sternohyoideus and the Sternothyreoideus; these have to be split and retracted one after the other, before the sheath of the vessel is reached. In doing this, care must be taken not to wound the anterior jugular vein, which crosses the Sternohyoideus to the external jugular or subclavian vein. The sheath must be opened on its medial or tracheal side, so as to avoid the internal jugular vein. Special care is necessary on the left side, where the artery is commonly overlapped by the vein; on the right side there is usually an interval between the artery and the vein, and the risk of wounding the latter is less.

Brasdor's method of ligaturing an artery on the distal side of an aneurysm is particularly suitable for the cure of aneurysm at the lower part of the common carotid, since no branches are given off from the artery between the aneurysm and the ligature.

Collateral Circulation.—After ligature of the common carotid, the collateral circulation may be perfectly established by the free communication which exists between the vessels of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery. The chief communications outside the cranium take place between the superior and inferior thyreoid arteries, and between the ramus cervicis and ramus descendens of the occipital; the vertebral takes the place of the internal carotid within the cranium.

Wounds of the common carotid should be treated by suture whenever possible, because, after ligature of the vessel, hemiplegia or other symptom of cerebral disturbance supervenes in about twenty-five per cent. of cases.

The External Carotid Artery

The **external carotid artery** (fig. 660) begins opposite the upper border of the thyreoid cartilage, at the level of the disc between the third and fourth cervical vertebræ, and, taking a slightly curved course, passes upwards and forwards, and then inclines backwards to a point behind the neck of the mandible, where it divides into the superficial temporal and internal maxillary arteries. It diminishes rapidly in size, owing to the number and large size of the branches given off from it. In the child, it is somewhat smaller than the internal carotid; but in the adult, the two vessels are of nearly equal size. At its origin, this artery is more superficial, and placed nearer the middle line than the internal carotid artery, and is contained within the carotid triangle.

Relations.—The external carotid artery is *covered by* the skin, superficial fascia, platysma, deep fascia, and anterior margin of the Sternocleidomastoideus; it is crossed by the Digastricus and Stylohyoideus, the hypoglossal nerve and its vena comitans, the lingual and the common facial veins, and sometimes by the superior thyreoid veins, higher up it passes into the substance of the parotid gland, where it is deep to the facial nerve and the junction of the superficial temporal and internal maxillary veins. *Medial* to it are the hyoid bone, the wall of the pharynx, the superior laryngeal nerve, and a portion of the parotid gland. *Lateral* to it, in the lower part of its course, is the internal carotid artery. Higher up it is separated from the internal carotid artery by the styloid process or stylohyoid muscle, the Styloglossus and Stylopharyngeus muscles, the glossopharyngeal nerve, and pharyngeal branch of the vagus nerve, and part of the parotid gland.

Applied Anatomy.—Ligature of the external carotid may be required in cases of wound of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumours of the scalp or face. It is also done as a preliminary measure to excision of the maxilla or tonsil. The seat of election for ligature is between the origins of the superior thyreoid and lingual branches, about a finger's breadth below the tip of the greater cornu of the hyoid bone. To tie the vessel, an incision is made from the angle of the mandible to the upper border of the thyreoid cartilage, and the superficial tissues and deep fascia divided. The anterior border of the Sternocleidomastoideus must be retracted and the lower border of the parotid gland raised, so as to expose the tendon of the Digastricus and the hypoglossal nerve, which cross the artery. The great difficulty in this is due to the plexus of veins derived from the superior thyreoid and lingual veins, which overlie the artery; if necessary, these must be ligatured and divided. Care must be taken not to mistake the lingual and external maxillary arteries, when they arise by a common trunk, as they sometimes do, for the external carotid artery. The needle is to be passed from the lateral to the medial side of the vessel, carefully avoiding the superior laryngeal nerve, which lies in close proximity to the artery.

Collateral Circulation.—The circulation is re-established by the free communication between most of the large branches of the artery (external maxillary, lingual, superior thyreoid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid artery, and of the occipital and with branches of the subclavian, &c.

The Branches of the External Carotid Artery (figs. 660, 663)

The branches of the external carotid artery are:

1. Superior thyreoid.
2. Ascending pharyngeal.
3. Lingual.
4. External maxillary.
5. Occipital.
6. Posterior auricular.
7. Superficial temporal.
8. Internal maxillary.

1. The **superior thyreoid artery** (fig. 660) arises from the external carotid just below the level of the greater cornu of the hyoid bone and ends in the thyreoid gland.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Relations.—From its origin beneath the anterior border of the St mastoideus it runs upwards and forwards for a short distance in the triangle, where it is covered by the skin, Platysma, and fascia; it p downwards beneath the Omohyoideus, Sternohyoideus, and Sternoth To its medial side are the Constrictor pharyngis inferior and the exter of the superior laryngeal nerve.

FIG. 663.—Plan of the branches of the external carotid artery.

Branches.—It distributes the adjacent muscles, and bran thyreoid gland; it anastomoses fellow of the opposite side, and inferior thyreoid arteries. The to the gland are generally two to an anterior and a posterior; the and larger branch supplies the anterior surface; on the of the gland it anastomoses corresponding artery of the side; the posterior branch des the posterior surface of the gl anastomoses with the inferior artery.

Besides the arteries distrib the muscles and to the thyreoid the superior thyreoid artery supp following branches:

Hyoid.
Sternocleidomastoid.
Superior laryngeal.
Cricothyreoid.

The **hyoid branch** is small a along the lower border of the hy beneath the Thyreohyoideus, and anastomoses with the vessel of the side.

The **sternocleidomastoid branch** frequently arises from the external artery; it runs downwards and lateralwards across the sheath of the carotid artery, and enters the Sternocleidomastoideus.

The **superior laryngeal artery**, larger than either of the preceding, is quently a separate branch of the external carotid artery; it accompa internal laryngeal branch of the superior laryngeal nerve, beneath the hyoideus; it pierces the lower part of the hyothyreoid membrane, and supp muscles, mucous membrane and glands of the larynx, anastomosing w artery of the opposite side, and with the inferior laryngeal branch of the thyreoid artery.

The **cricothyreoid branch** is small and runs transversely across the upp of the cricothyreoid membrane, communicating with the artery of the oppo

Applied Anatomy.—The superior thyreoid artery, or one of its branches, divided in cases of cut throat, giving rise to considerable hæmorrhage. The thyreoid is ligatured in cases of bronchocele where the removal of a lobe of the gland may present special dangers.

The position of the sternocleidomastoid branch is of importance in connexion the operation of ligature of the common carotid artery. It crosses and lies on the of this vessel and may chance to be wounded in opening the sheath. The position cricothyreoid branch should be remembered, as it may prove the source of tro hæmorrhage during the operation of laryngotomy.

2. The **ascending pharyngeal artery** (fig. 668), the smallest bran the external carotid artery, is a long, slender vessel, deeply seated in the It arises close to the origin of the external carotid artery, and ascends cally between the internal carotid artery and the side of the pharynx under surface of the base of the skull, lying on the Longus capitis; it anast freely with the ascending palatine branch of the external maxillary arte

Its branches are:

Pharyngeal. Inferior tympanic. Posterior meningeal.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **pharyngeal branches** are three or four in number. Two of these descend
upply the Constrictores pharyngis medius et inferior and the Stylopharyngeus,
ying in their substance and in the underlying mucous membrane. A branch of
he size is distributed to the palate, and may take the place of the ascending
o branch of the external maxillary artery; it runs downwards and forwards
n the superior border of the Constrictor pharyngis superior and the Levator
alatini, and accompanies the latter muscle to the soft palate; it gives branches
o tonsil, and supplies a twig to the auditory tube.

The **inferior tympanic artery** is a small branch which passes through the inferior
anic canaliculus of the temporal bone, in company with the tympanic branch
he glossopharyngeal nerve, to supply the medial wall of the tympanic cavity
nastomose with the other tympanic arteries.

The **meningeal branches** are several small vessels which supply the dura mater.
the *posterior meningeal*, enters the cranium through the foramen lacerum;
ond passes through the jugular foramen; and occasionally a third through
anal for the hypoglossal nerve.

Numerous small vessels supply the Longi capitis et colli, the sympathetic trunk,
ypoglossal and vagus nerves, and the lymph-glands; they anastomose with
ascending cervical and vertebral arteries.

The **lingual artery** (fig. 668) arises from the external carotid artery
n the superior thyreoid and external maxillary arteries; it runs
ely upwards and medialwards to the greater cornu of the hyoid bone,
then curves downwards and forwards, forming a loop which is crossed by
ypoglossal nerve; it passes beneath the Digastricus and Stylohyoideus,
horizontally forwards beneath the Hyoglossus, and finally, ascending
st perpendicularly to the tongue, courses forwards on its lower surface as
as the tip.

Relations.—Its first portion is contained within the carotid triangle; it rests
the Constrictor pharyngis medius, and is under cover of the Platysma and
fascia of the neck. Its second portion also lies upon the Constrictor
ngis medius, being at first under cover of the tendon of the Digastricus
the Stylohyoideus, and afterwards of the Hyoglossus. Its third portion
between the Hyoglossus and Genioglossus. The fourth or terminal part,
the name of the *arteria profunda linguæ* (ranine artery), runs along the inferior
e of the tongue to its tip, covered only with the mucous membrane; above
the Longitudinalis inferior, and medial to it the Genioglossus. The hypoglossal
e crosses the first part of the lingual artery, but is separated from the second
by the Hyoglossus.

The branches of the lingual artery are:

Hyoid.	Sublingual.
Rami dorsales linguæ.	Arteria profunda linguæ.

The **hyoid branch** is very small; it runs along the upper border of the hyoid
supplying the muscles attached to the bone, and anastomosing with its fellow
e opposite side.

The **rami dorsales linguæ** consist usually of two or three small branches; they
beneath the Hyoglossus, ascend to the posterior part of the dorsum of the
e, and supply the mucous membrane of the tongue, the glossopalatine arch,
alatine tonsil, soft palate, and epiglottis; they anastomose with the vessels
e opposite side.

The **sublingual artery** arises at the anterior margin of the Hyoglossus, and
forward between the Genioglossus and Mylohyoideus to the sublingual gland.
ies the gland and gives branches to the Mylohyoideus and neighbouring
s, and to the mucous membrane of the mouth and gums. One branch
behind the alveolar part of the mandible in the substance of the gum to
ose with a similar artery from the other side; another pierces the Mylo-
s and anastomoses with the submental branch of the external maxillary

The **arteria profunda linguæ** (ranine artery) is the terminal portion of the lingual
; it pursues a tortuous course and runs along the under surface of the tongue
side of the frenulum linguæ, between the Longitudinalis linguæ inferior and
ucous membrane; it lies on the lateral side of the Genioglossus, accompanied
the lingual nerve.

Applied Anatomy.—The lingual artery is not infrequently divided near its origin in cases of cut throat; while severe hæmorrhage, which cannot be restrained by ordinary means, may ensue from a wound, or deep ulcer, of the tongue. In the former case the primary wound may be enlarged if necessary, and the bleeding vessel secured; in the latter, it has been suggested that the lingual artery should be tied near its origin.

Ligature of the lingual artery (fig. 662, B) has been practised as a preliminary to removal of the tongue. The operation is a difficult one on account of the size of the artery, the number of important parts by which it is surrounded, and its irregularity of origin. An incision is to be made in a curved direction from the breadth behind the symphysis menti downwards to the cornu of the hyoid bone, and upwards to near the angle of the mandible. Care must be taken not to carry the incision too far backwards, for fear of endangering the anterior facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. This is then to be incised and the submaxillary gland exposed and pulled upwards. A triangular space is now seen, bounded in front by the posterior border of the Mylohyoid, below and behind by the tendon of the Digastricus, and above by the hypoglossal. The floor of the space is formed by the Hyoglossus, beneath which the artery lies. The parts are to be drawn forwards by a blunt hook inserted beneath the tendon of the Digastricus, and the fibres of the Hyoglossus cut through horizontally just above the Digastricus. The artery will then be exposed lying on the Constrictor pharyngis medius, and in passing the aneurysm needle, care must be taken not to pierce the latter. The hypoglossal nerve must also be avoided.

Troublesome hæmorrhage may occur in the division of the frenulum linguæ in case if the aa. profundæ linguæ, which lie one on either side of it, be wounded. This operation should always be performed with a pair of blunt-pointed scissors, and the mucous membrane alone divided by a very superficial cut, which cannot endanger any vessel. The further liberation of the tongue which may be necessary can be effected by tearing.

4. The **external maxillary artery** (facial artery) (fig. 664) arises from the external carotid artery in the carotid triangle a little above the lingual. Sheltered by the ramus of the mandible, it passes obliquely up beneath the Digastricus and Stylohyoideus, above which it arches to enter a groove on the posterior border of the submaxillary gland. It then curves upwards on the body of the mandible at the antero-inferior angle of the Masseter; forwards and upwards across the cheek to the angle of the mouth, then along the side of the nose, and ends as the *angular artery* at the palpebral commissure. The external maxillary artery is remarkably tortuous in the neck to accommodate itself to the movements of the pharynx in deglutition, and on the face to the movements of the mandible, lips, cheeks.

Relations.—*In the neck*, its origin is superficial, being placed under cover of skin, Platysma, and fascia; it then passes beneath the Digastricus and Stylohyoid muscles and part of the submaxillary gland, and frequently beneath the hypoglossal nerve. It lies upon the Constrictores pharyngis medius et superior, the latter which separates it, at the summit of its arch, from the lower and posterior part of the tonsil. *On the face*, where it passes over the body of the mandible, it is comparatively superficial, lying immediately beneath the Platysma. In its course over the face, it is under cover of the skin, the fat of the cheek, and, near the angle of the mouth, the Platysma, Risorius, and Zygomaticus. It rests on the Buccinator and Caninus, and passes either over or through the infra-orbital head of the Quadratus labii superioris. The anterior facial vein lies posterior to the artery, and takes a more direct course across the face, where it is separated from the artery by a considerable interval; in the neck it lies superficial to the artery. The branches of the facial nerve cross the artery from behind forwards.

The branches of the external maxillary artery may be divided into two sets: those given off in the neck (cervical), and those on the face (facial).

Cervical branches.	*Facial branches.*
Ascending palatine.	Inferior labial.
Tonsillar.	Superior labial.
Glandular.	Lateral nasal.
Submental.	Angular.

The **ascending palatine artery** (fig. 668) arises close to the origin of the external maxillary artery and passes up between the Styloglossus and Stylopharyngeus to the side of the pharynx, along which it is continued between the Constrictor pharyngis superior and the Pterygoideus internus towards the base of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the Levator veli palatini it divides into two branches: one follows the course is muscle, and, winding over the upper border of the Constrictor pharyngis supplies the soft palate and the palatine glands, anastomosing with its of the opposite side and with the descending palatine branch of the internal ry artery; the other pierces the Constrictor pharyngis superior and supplies latine tonsil and auditory tube, anastomosing with the tonsillar and ascending ngeal arteries.

Fig. 664.—The arteries of the right side of the face and scalp.

The **tonsillar branch** (fig. 668), sometimes derived from the ascending palatine ry, ascends between the Pterygoideus internus and Styloglossus, and then g the side of the pharynx; it perforates the Constrictor pharyngis superior and tes in the palatine tonsil and the root of the tongue.

The **glandular branches**, three or four large vessels, supply the submaxillary ary gland and lymph-glands, the neighbouring muscles, and the skin.

The **submental artery**, the largest cervical branch of the external maxillary ry, springs from that artery just as it quits the submaxillary gland: it runs wards upon the Mylohyoideus, below the body of the mandible, and beneath anterior belly of the Digastricus. It supplies the surrounding muscles, and stomoses with the sublingual artery and with the mylohyoid branch of the or alveolar artery; at the chin it turns upwards over the inferior border of mandible and divides into a superficial and a deep branch. The superficial ch passes between the skin and the Quadratus labii inferioris, and anastomoses the inferior labial artery; the deep branch runs between the muscle and bone, supplies the lip, and anastomoses with the inferior labial and mental ries.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **inferior labial artery** (inferior coronary artery) arises near the the mouth; it passes upwards and forwards beneath the Triangularis, and trating the Orbicularis oris, runs in a tortuous course near the edge of the between this muscle and the mucous membrane. It supplies the gland membrane and muscles of the lower lip; and anastomoses with the artery opposite side, and with the mental branch of the inferior alveolar artery.

The **superior labial artery** (superior coronary artery) is larger and more than the inferior. It follows a similar course near the edge of the upper between the mucous membrane and the Orbicularis oris, and anastomoses the artery of the opposite side. It supplies the upper lip, and gives off *branch* which ramifies on the lower and front part of the nasal septum, and *branch* which supplies the ala of the nose.

The **lateral nasal branch** is derived from the external maxillary artery vessel ascends along the side of the nose. It supplies the ala and dorsum nose anastomosing with its fellow, with the septal and alar branches dorsal nasal branch of the ophthalmic artery, and with the infra-orbital the internal maxillary artery.

The **angular artery** is the terminal part of the external maxillary ascends to the medial angle of the eye, imbedded in the fibres of the of the Quadratus labii superioris, and accompanied by the angular vein. cheek it anastomoses with the infra-orbital artery, and, after supplying the sac and Orbicularis oculi, ends by anastomosing with the dorsal nasal branch ophthalmic artery.

The anastomoses of the external maxillary artery are very numerous, with the branches of the vessel of the opposite side, but, *in the neck*, with the lingual branch of the lingual, with the ascending pharyngeal, and with the branch of the internal maxillary; *on the face*, with the mental branch of the alveolar, the transverse facial branch of the superficial temporal, the infra- branch of the internal maxillary, and the dorsal nasal branch of the ophthal

Peculiarities.—The external maxillary artery not infrequently arises in common the lingual artery. It varies in size, and in the extent to which it supplies the occasionally ends as the submental, and not infrequently extends only as high as the of the mouth or nose. The deficiency is then compensated for by enlargement of the neighbouring arteries.

Applied Anatomy.—The passage of the external maxillary artery over the the mandible would appear to afford a favourable position for the application of in cases of hæmorrhage from the lips; but such application is useless, except for short time, on account of the free communication of the artery with its fellow, and numerous branches from different sources. In a wound involving the lip, it is seize the part between the fingers, and evert it, when the bleeding vessel may be secured with pressure-forceps. In order to prevent hæmorrhage during the growths from the lip, the latter should be compressed on either side between the and thumb, or by a pair of specially devised clamp-forceps, while the surgeon diseased part. In order to stop hæmorrhage when the lip has been divided in tion, it is necessary, when closing the wound, to pass the sutures through the almost as deep as its mucous surface, because the labial arteries run in the layer of the lips; by these means, not only are the cut surfaces more neatly and adapted to each other, but the possibility of hæmorrhage is prevented by including divided artery in the suture. If, on the contrary, the suture be passed through the cutaneous portion of the wound, hæmorrhage occurs into the cavity of the The student should observe that the angular artery ascends on the nasal side lacrimal sac; in operating for fistula lacrimalis, the sac should always be opened lateral side, in order to avoid this vessel.

The external maxillary artery is separated from the lower and hinder part of the by the Constrictor pharyngis superior, and may be wounded in operations in that

The free anastomosis of the branches of the external maxillary artery contrib the success of plastic operations on the face.

5. The **occipital artery** (fig. 664) arises from the posterior part of external carotid artery, opposite to the external maxillary artery, and the lower margin of the posterior belly of the Digastricus; it ends in posterior part of the scalp.

Relations.—At its origin, it is under cover of the posterior belly of the Digastricus and the Stylohyoideus, and the hypoglossal nerve winds round it from behind forwards; higher up, it crosses the internal carotid artery, the internal jugular vein, and the vagus and accessory nerves. It next ascends along the lower bord

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

posterior belly of the Digastricus to the interval between the transverse process the atlas vertebra and the mastoid process of the temporal bone, and passes zontally backwards, grooving the surface of the latter bone, being covered by Sternocleidomastoideus, Splenius capitis, Longissimus capitis, and Digastricus, sting upon the Rectus capitis lateralis, Obliquus superior, and Semispinalis It then runs vertically upwards, pierces the fascia connecting the cranial chment of the Trapezius with the Sternocleidomastoideus, and ascends in a uous course in the superficial fascia of the scalp, where it divides into numerous ches. Its terminal portion is accompanied by the greater occipital nerve.

The branches of the occipital artery are:

Sternocleidomastoid.	Auricular.	Meningeal.
Mastoid.	Muscular.	Occipital.
	Ramus descendens.	

The **sternocleidomastoid branch** generally arises from the beginning of the occipital ry, but sometimes springs directly from the external carotid artery. It passes wards and backwards over the hypoglossal nerve, and enters the sub- e of the Sternocleidomastoideus, in company with the accessory nerve; it stomoses with the sternocleidomastoid branch of the superior thyreoid artery.

The **mastoid branch**, small in size and sometimes absent, enters the cranial through the mastoid foramen; it gives branches to the mastoid air-sinuses e dura mater, and anastomoses with the middle meningeal artery.

The **auricular branch** supplies the back of the concha and anastomoses with sterior auricular artery.

Muscular branches are supplied to the Digastricus, Stylohyoideus, Splenius, and issimus capitis.

The **ramus descendens** (arteria princeps cervicis) (fig. 668) arises from the al artery as the latter lies on the Obliquus superior, and divides into a rficial and a deep branch. The superficial branch passes beneath the Splenius, anastomoses with the ascending branch of the transverse cervical artery; the branch descends between the Semispinales capitis et colli, and anastomoses the vertebral artery, and with the arteria profunda cervicalis, a branch of the vertebral trunk. The anastomosis between these vessels assists in establishing llateral circulation after ligature of the common carotid or subclavian artery.

The **meningeal branches** ascend with the internal jugular vein, and enter the through the jugular foramen and condyloid canal, to supply the dura mater e posterior fossa.

The **occipital branches**, the terminal branches, are distributed to the scalp, and as high as the vertex of the skull; they are very tortuous, and lie between kin and the Occipitalis, anastomosing with the artery of the opposite side and the posterior auricular and temporal arteries, and supplying the Occipitalis, kin, and the pericranium. One of the terminal branches may give off a ngeal twig which passes through the parietal foramen.

The **posterior auricular artery** (fig. 664) is small and arises from the nal carotid artery immediately above the Digastricus and Stylohyoideus. ends, under cover of the parotid gland, on the styloid process of the oral bone, to the groove between the cartilage of the auricula and the oid process, where it divides into auricular and occipital branches.

In addition to supplying small branches to the Digastricus, Stylohyoideus, rnocleidomastoideus, and parotid gland, this vessel gives off the three wing branches:

Stylomastoid.	Auricular.	Occipital.

The **stylomastoid artery** enters the stylomastoid foramen and supplies the panic cavity, the tympanic antrum, the mastoid air-sinuses, and the semicircular als. In the young subject a branch from this vessel forms, with the anterior panic artery from the internal maxillary, a vascular circle which surrounds supplies small vessels to the deep surface of the tympanic membrane. It stomoses with the superficial petrosal branch of the middle meningeal artery a twig which enters the hiatus canalis facialis.

The **auricular branch** ascends beneath the Auricularis posterior, and ramifies the back of the auricula; some of its branches pierce the auricula, and others e round its margin to supply its lateral surface. It anastomoses with the ral and anterior auricular branches of the superficial temporal artery.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **occipital branch** passes backwards over the Sternocleidomastoid, the Occipitalis muscle and the scalp above and behind the ear; it anastomoses with the occipital artery.

7. The **superficial temporal artery** (fig. 664), the smaller terminal branch of the external carotid artery, begins in the parotid gland, behind the neck of the mandible, and crosses over the posterior root of the zygomatic process of the temporal bone; about 5 cm. above this process it divides into a frontal and a parietal branch.

Relations.—As it crosses the zygomatic process, it is covered by the Auricularis anterior; it is crossed by the temporal and zygomatic branches of the facial nerve and is accompanied by the auriculotemporal nerve, which lies immediately behind it.

It supplies some twigs to the parotid gland, the mandibular joint, and the Masseter, and gives off the following branches:

Transverse facial.	Zygomatico-orbital.	Frontal.
Anterior auricular.	Middle temporal.	Parietal.

The **transverse facial artery** (fig. 664) arises from the superficial temporal artery before that vessel quits the parotid gland; it runs forwards through the substance of the gland, passes across the Masseter between the parotid duct and the zygomatic arch, accompanied by one or two branches of the facial nerve. It divides into numerous branches which supply the parotid gland and the Masseter, and the skin, and anastomose with the external maxillary, masseteric, buccinator, and infra-orbital arteries.

The **anterior auricular branches** are distributed to the lobule and anterior part of the auricula, and to the external acoustic meatus; they anastomose with the posterior auricular artery.

The **zygomatico-orbital artery,** sometimes a branch of the middle temporal artery, runs along the upper border of the zygomatic arch between the two layers of the temporal fascia to the lateral angle of the orbit. It supplies branches to the Orbicularis oculi, and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery.

The **middle temporal artery** arises immediately above the zygomatic arch and, perforating the temporal fascia, gives branches to the Temporalis; it anastomoses with the deep temporal branches of the internal maxillary artery.

The **frontal branch** runs tortuously upwards and forwards towards the frontal tuberosity; it supplies the muscles, skin, and pericranium in this region, and anastomoses with its fellow of the opposite side, and with the supra-orbital and frontal arteries.

The **parietal branch,** larger than the frontal, curves upwards and backwards on the side of the head, lying superficial to the temporal fascia, and anastomoses with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

Applied Anatomy.—As the superficial temporal artery crosses the zygomatic process it lies beneath the skin and fascia, and its pulsations may be readily felt during administration of an anæsthetic, or under circumstances where the radial pulse is not available; it may be easily compressed against the bone in order to check bleeding from the temporal region of the scalp. When a flap is raised from this part of the head in trephining, the incision should be shaped like a horseshoe, with its convexity upwards, so that the flap shall contain the superficial temporal artery, which ensures a free supply of blood.

8. The **internal maxillary artery** (figs. 665, 666), the larger terminal branch of the external carotid artery, arises behind the neck of the mandible and is at first imbedded in the parotid gland; it passes forwards between the ramus of the mandible and the sphenomandibular ligament, and then runs either upon or beneath the Pterygoideus externus, to the pterygopalatine fossa. It may be divided into mandibular, pterygoid, and pterygopalatine portions.

The *first or mandibular portion* passes horizontally forwards, between the neck of the mandible and the sphenomandibular ligament, where it lies parallel to and a little below the auriculotemporal nerve; it crosses the inferior alveolar nerve, and runs along the lower border of the Pterygoideus externus.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The *second or pterygoid portion* runs obliquely forwards and upwards under the lower of the Temporalis, and superficial to the lower head of the Pterygoideus

FIG. 665.—The right internal maxillary artery.

FIG. 666.—A plan of the branches of the internal maxillary artery.

externus; very frequently it lies beneath the latter muscle between it and the branches of the mandibular nerve.

The *third or pterygopalatine portion* passes between the upper and lower heads of the Pterygoideus externus, and through the pterygomaxillary fissure

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

into the pterygopalatine fossa, where it lies in front of the sphenopa ganglion.

The branches of the vessel may be divided into three groups (fig corresponding with its three portions.

The Branches of the First or Mandibular Portion of the Internal Maxillary Artery (fig. 666)

Deep auricular.
Anterior tympanic.
Middle meningeal.
Accessory meningeal.
Inferior alveolar.

The **deep auricular artery**, a small branch, often arises in common w anterior tympanic. It ascends in the substance of the parotid gland, be temporomandibular joint, pierces the cartilaginous or bony wall of the e acoustic meatus, and supplies its cuticular lining and the outer surface tympanic membrane; it gives a branch to the mandibular joint.

The **anterior tympanic artery**, a small branch, ascends behind the ma joint, and enters the tympanic cavity through the petrotympanic fiss ramifies upon the tympanic membrane, and forms a vascular circle arou with the stylomastoid branch of the posterior auricular artery; it anast with the artery of the pterygoid canal and with the caroticotympanic branc the internal carotid artery.

The **middle meningeal artery** is the largest of the meningeal arteries. It between the sphenomandibular ligament and the Pterygoideus externus and the two roots of the auriculotemporal nerve, and enters the cranial through the foramen spinosum of the sphenoidal bone; it then runs for and lateralwards for a variable distance in a groove on the anterior part squama of the temporal bone, and divides into an anterior and a posterior b The *anterior branch*, the larger, crosses the great wing of the sphenoidal bone, the groove, or canal, in the sphenoidal angle of the parietal bone, and then into branches which spread out between the dura mater and internal surf the cranium, some passing upwards as far as the vertex, and others backwa the occipital region. The *posterior branch* curves backwards on the squam temporal bone, and, reaching the squamous border of the parietal bone some in front of its mastoid angle, divides into branches which supply the posteri of the dura mater and cranium. The branches of the middle meningeal a anastomose with the arteries of the opposite side, and with the anterior and po meningeal arteries. One branch runs forwards and anastomoses with the rec meningeal branch of the lacrimal artery; an enlargement of this anast explains the occasional origin of the lacrimal artery from the middle men artery.

The middle meningeal artery gives off the following branches within the cranial c 1. Numerous small *ganglionic branches* supply the semilunar ganglion and the roots trigeminal nerve. 2. A *superficial petrosal branch* enters the hiatus of the facial c gives twigs to the facial nerve and the tympanic cavity, and anastomoses with the mastoid branch of the posterior auricular artery. 3. A *superior tympanic artery* the semicanal for the Tensor tympani, and supplies this muscle and the lining me of the canal. 4. *Temporal branches* pass through foramina in the great wing of the sp and anastomose in the temporal fossa with the deep temporal arteries.

Applied Anatomy.—The middle meningeal artery is of considerable surgical im tance, as it may be torn in fractures of the temporal region of the skull, or, inde injuries causing separation of the dura mater from the bone without fracture. The may be followed by considerable hæmorrhage between the bone and dura mater, which duces symptoms of compression of the brain, and requires trephining for its relief (p. As the compression implicates the motor region of the cortex, paralysis on the opp side of the body forms the prominent symptom of the lesion. The anterior bran this artery lies in a groove or a bony canal on the sphenoidal angle of the parietal bo a point 4 cm. behind the zygomatic process of the frontal bone, and 4·5 cm. above zygomatic arch. From this point it passes upwards and slightly backwards to the sag suture, lying about 1·25 to 2 cm. behind the coronal suture. The posterior branch backwards over the squama of the temporal bone. In order to expose the anterior bra of the artery, a point is taken 4 cm. above the zygomatic arch and the same distance be the zygomatic process of the frontal bone. Here the pin of the trephine is to be ap

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

horseshoe-shaped flap, measuring 8 cm. in length and transversely, and consisting of all structures of the scalp down to and including the pericranium, is first made, with its just above the zygomatic arch. This flap is reflected and a 2·5 cm. trephine applied. the circle of bone has been removed, the blood-clot is exposed, and gently got rid of, possible the bleeding point must be found and controlled.

The **accessory meningeal branch** may arise from the internal maxillary artery from the middle meningeal artery. It enters the cranial cavity through the foramen ovale, and supplies branches to the semilunar ganglion and the dura mater.

The **inferior alveolar artery** (inferior dental artery) descends with the inferior alveolar nerve to the mandibular foramen on the medial surface of the ramus of the mandible. It runs in the mandibular canal, accompanied by the inferior alveolar nerve, and, opposite the first premolar tooth, divides into two branches, incisor and mental. The *incisor* branch is continued forwards below the incisor teeth as far as the middle line, where it anastomoses with the artery of the opposite side; the inferior alveolar artery and its incisor branch give off a few twigs to the mandible, and a series of branches which correspond in number to the roots of the teeth; these enter the minute apertures at the extremities of the roots, and supply the pulp of the teeth. The *mental* branch escapes at the mental foramen, supplies the chin, and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a *lingual* branch which descends with the lingual nerve and supplies the mucous membrane of the mouth. Before the inferior alveolar artery enters the mandibular foramen, it gives off a *mylohyoid* branch which pierces the sphenomandibular ligament, and descends with the mylohyoid nerve in the mylohyoid groove on the ramus of the mandible; it ramifies on the superficial surface of the Mylohyoideus and anastomoses with the submental branch of the external maxillary artery.

The Branches of the Second or Pterygoid Portion of the Internal Maxillary Artery (fig. 666)

Deep temporal. Pterygoid. Masseteric. Buccinator.

The **deep temporal branches,** an anterior and a posterior, ascend between the Temporalis and the pericranium; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and great wing of the sphenoidal bone.

The **pterygoid branches,** irregular in their number and origin, supply the Pterygoidei.

The **masseteric artery** is small and passes with the masseteric nerve behind the tendon of the Temporalis, and through the mandibular notch to the deep surface of the Masseter. In the substance of that muscle it anastomoses with the masseteric branches of the external maxillary artery and with branches of the transverse facial artery.

The **buccinator artery** is small and runs obliquely forwards with the buccinator nerve, between the Pterygoideus internus and the insertion of the Temporalis, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the external maxillary and infra-orbital arteries.

The Branches of the Third or Pterygopalatine Portion of the Internal Maxillary Artery (fig. 666)

Posterior superior alveolar. Pharyngeal.
Infra-orbital. Artery of the pterygoid canal.
Descending palatine. Sphenopalatine.

The **posterior superior alveolar artery** (posterior dental artery) is given off from the internal maxillary artery as that vessel enters the pterygopalatine fossa; it frequently arises in conjunction with the infra-orbital artery. Descending upon the infratemporal surface of the maxilla, it divides into branches, some of which supply the molar and premolar teeth and the lining of the maxillary sinus, while others are continued forwards on the alveolar process to supply the gums.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **infra-orbital artery** often arises in conjunction with the posterior alveolar artery. It enters the orbital cavity through the posterior part of the orbital fissure, runs along the infra-orbital groove and canal with the infra-orbital nerve, and emerges with the nerve on the face through the infra-orbital foramen beneath the infra-orbital head of the Quadratus labii superioris. While in the canal, it gives off (*a*) *orbital* branches which assist in supplying the Rectus inferior and Obliquus inferior and the lacrimal sac, and (*b*) *anterior superior alveolar* branches which descend through the anterior alveolar canals to supply the upper incisor and canine teeth and the mucous membrane of the maxillary sinus. On the face the branches ascend to the medial angle of the orbit and the lacrimal sac, anastomose with the angular branch of the external maxillary artery; others run towards the nose, anastomosing with the dorsal nasal branch of the ophthalmic artery, and others descend between the Quadratus labii superioris and the Canine and anastomose with the external maxillary, transverse facial, and buccal arteries.

The remaining branches of the internal maxillary artery arise from that part of the artery which is contained in the pterygopalatine fossa.

The **descending palatine artery** descends through the pterygopalatine ganglion, and with the anterior palatine branch of the sphenopalatine ganglion, and gives two or three *smaller palatine arteries* which are transmitted through the palatine canals to supply the soft palate and palatine tonsil, and to anastomose with the ascending palatine artery. The continuation of the vessel is now the *greater palatine artery*; it emerges on the oral surface of the palate through the greater palatine foramen, runs forwards in a groove near the alveolar border of the hard palate to the incisive canal; its terminal part passes upwards through this canal, and anastomoses with a branch of the sphenopalatine artery. Branches are distributed to the gums, the palatine glands, and the mucous membrane of the roof of the mouth.

Applied Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as it is in danger of being wounded, and may give rise to formidable hæmorrhage; it has even been found necessary to plug the pterygopalatine canal in order to arrest the bleeding.

The **pharyngeal branch** is very small; it runs backwards through the pharyngeal canal with the pharyngeal nerve, and is distributed to the roof of the nose and pharynx, to the sphenoidal air-sinus, and the auditory tube.

The **artery of the pterygoid canal** (Vidian artery), frequently a branch of the descending palatine artery, passes backwards along the pterygoid canal with the corresponding nerve. It is distributed to the upper part of the pharynx and to the auditory tube, and sends into the tympanic cavity a small branch which anastomoses with the other tympanic arteries.

The pharyngeal branch and the artery of the pterygoid canal lie on the medial and lateral aspects respectively of the sphenopalatine ganglion, while the trunk of the internal maxillary artery is in front of it.

The **sphenopalatine artery** is really the terminal part of the internal maxillary artery; it passes through the sphenopalatine foramen into the cavity of the nose at the posterior part of the superior meatus. Here it gives off its *posterior lateral nasal* branches which ramify over the conchæ and meatuses, anastomose with the ethmoidal arteries and the nasal branches of the descending palatine artery, and assist in supplying the frontal, maxillary, ethmoidal, and sphenoidal air-sinuses. Crossing the anterior part of the under surface of the sphenoidal bone, the sphenopalatine artery ends on the nasal septum as the *posterior septal* branches, which anastomose with the ethmoidal arteries and the septal branch of the superior labial artery; one branch descends in a groove on the vomer to the incisive canal and anastomoses with the terminal ascending branch of the greater palatine artery.

The Triangles of the Neck (fig. 667)

The side of the neck presents a somewhat quadrilateral outline, limited above, by the lower border of the body of the mandible, and a line drawn

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

from the angle of the mandible to the mastoid process; below, by the upper border of the clavicle; in front, by the middle line of the neck; behind, by the anterior margin of the Trapezius. This space is subdivided by the Sternocleidomastoideus, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process and occipital bone above. The space in front of this muscle is called the *anterior triangle* of the neck; that behind it, the *posterior triangle*.

The Anterior Triangle of the Neck (fig. 667)

The anterior triangle of the neck is bounded anteriorly by the middle line of the neck, posteriorly, by the anterior margin of the Sternocleidomastoideus; its base, directed upwards, is formed by the lower border of the body of the mandible, and a line from the angle of the mandible to the mastoid process: its apex is below, at the sternum. This triangle is subdivided into muscular, carotid, submaxillary, and suprahyoid triangles.

Fig. 667.—The triangles of the neck.

The muscular, or inferior carotid, triangle is bounded, in front, by the median line of the neck from the hyoid bone to the sternum; behind and below, by the anterior margin of the Sternocleidomastoideus; behind and above, by the superior belly of the Omohyoideus. It is covered by the skin, superficial fascia, Platysma, and deep fascia, ramifying in which are some of the branches of the cutaneous cervical and supraclavicular nerves. Beneath these superficial structures are the Sternohyoideus and Sternothyreoideus, which, together with the anterior margin of the Sternocleidomastoideus, conceal the lower part of the carotid sheath and its contents. In front of the sheath are a few descending filaments from the ansa hypoglossi; behind the sheath are the inferior thyreoid artery, the recurrent nerve, and the sympathetic trunk; and on its medial side, the œsophagus, the trachea, the thyreoid gland, and the lower part of the larynx.

The carotid triangle is limited, behind, by the Sternocleidomastoideus; in front and below, by the superior belly of the Omohyoideus; and above, by the Stylohyoideus and the posterior belly of the Digastricus. It is covered by the skin, superficial fascia, Platysma, and deep fascia, ramifying in which are branches of the facial and the cutaneous cervical nerves. Its floor is formed by parts of the Thyreohyoideus, Hyoglossus, and the Constrictores pharyngis medius et inferior. When this space is dissected it is seen to contain the upper part of the common carotid artery, which divides opposite the superior border of the thyreoid cartilage into the external and internal carotid arteries. These vessels are overlapped by the anterior margin of the Sternocleidomastoideus. The external and internal carotid arteries lie side by side, the internal being the more anterior. The following branches of the external carotid artery are also met with: the superior thyreoid, running forwards and downwards; the lingual, directly forwards; the external maxillary,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

forwards and upwards; the occipital, backwards; and the ascending pha-geal, directly upwards on the medial side of the internal carotid. veins met with are: the internal jugular, which lies on the lateral of the common and internal carotid arteries; and veins corresponding the above-mentioned branches of the external carotid artery—viz. superior thyreoid, the lingual, common facial, ascending pharyngeal, sometimes the occipital—all of which end in the internal jugular. The hypoglossal nerve crosses both the internal and external carotid, curving round the origin of the occipital artery; in this position it gives descending ramus which runs down in front of the carotid sheath. In the sheath, between the common carotid artery and the internal jugular and behind both, is the vagus nerve; behind the sheath, the sympathetic trunk. The accessory nerve appears at the lower border of the posterior belly of the Digastricus, and descends for a short distance on the lateral of the vessels before it pierces the Sternocleidomastoideus. On the side of the external carotid artery, below the hyoid bone, is the internal branch of the superior laryngeal nerve; and, still more inferiorly, external branch of the same nerve. The upper portion of the and lower portion of the pharynx are also found in the anterior part triangle.

The **submaxillary, or digastric, triangle** is bounded, above, by lower border of the body of the mandible, and a line drawn from its to the mastoid process; below, by the posterior belly of the Digastricus, the Stylohyoideus; in front, by the anterior belly of the Digastricus. is covered by the skin, superficial fascia, Platysma, and deep fascia, rami in which are branches of the facial and cutaneous cervical nerves. Its is formed by the Mylohyoideus, Hyoglossus, and Constrictor pharyngis sup. It is divided into an anterior and a posterior part by the stylomandibular ligament. The anterior part contains the submaxillary gland, superficial which is the anterior facial vein, while imbedded in a groove on the posterior border of the gland is the external maxillary artery; beneath the gland, the surface of the Mylohyoideus, are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle contains the external carotid artery, which ascends deeply in the substance of the parotid gland; in this triangle the external carotid artery is in front of, and superficial to the internal carotid artery, and is crossed by the facial nerve; it gives off in its course the posterior auricular, superficial temporal, and internal maxillary branches: more deeply placed, and separated from the external carotid artery by the Styloglossus, the Stylopharyngeus, and the glossopharyngeal nerve, are the internal carotid artery, the internal jugular vein and the vagus nerve.

The **suprahyoid triangle** is limited on either side by the anterior belly of the Digastricus; its apex is at the mandible; its base is formed by the body of the hyoid bone, and its floor by the Mylohyoidei. It contains one two lymph-glands and some small veins; the latter unite to form the anterior jugular vein.

The Posterior Triangle of the Neck (fig. 667)

The **posterior triangle** of the neck is bounded, in front, by the Sternocleidomastoideus; behind, by the anterior margin of the Trapezius; its is formed by the middle one-third of the clavicle; its apex is at the occipital bone between the attachments of the Sternocleidomastoideus and the Trapezius. The triangle is crossed, about 2·5 cm. above the clavicle, by the inferior belly of the Omohyoideus, which divides the triangle into an occipital and a subclavian triangle.

The **occipital triangle**, the upper and larger division of the posterior triangle, is bounded in front by the Sternocleidomastoideus; behind, by the Trapezius; below, by the Omohyoideus. Its floor is formed from above downwards by the Splenius capitis, Levator scapulæ, and the Scaleni medius et posterior; sometimes a small part of the Semispinalis capitis is seen at the apex of the triangle. It is covered by the skin, the superficial and deep fascia

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

by the Platysma below. The accessory nerve pierces the Sternocleido-
oideus and is directed obliquely across the space to the under surface of
Trapezius; while the cutaneous and muscular branches of the cervical
s appear at the posterior border of the Sternocleidomastoideus; below,
upraclavicular nerves and the transverse cervical vessels and the upper
of the brachial plexus cross the space. A chain of lymph-glands is also
and running along the posterior border of the Sternocleidomastoideus, from
mastoid process to the root of the neck.

The **subclavian triangle**, the lower and smaller division of the posterior
angle, is bounded, above, by the inferior belly of the Omohyoideus; below,
the clavicle; its base is formed by the lower part of the posterior border
the Sternocleidomastoideus. Its floor consists of the first rib and the first
tation of the Serratus anterior. The size of this triangle varies with the
ent of attachment of the clavicular portions of the Sternocleidomastoideus
Trapezius, and also with the level at which the inferior belly of the
hyoideus crosses the neck; this level is lowered when the arm is raised,
raised when the arm is depressed. The triangle is covered by the skin,
superficial and deep fasciæ, and the Platysma, and crossed by the supra-
vicular nerves. Just above the level of the clavicle, the third portion of
subclavian artery curves lateralwards and downwards from the lateral
in of the Scalenus anterior, across the first rib, to the axilla. The sub-
vian vein lies behind the clavicle, and is not usually seen in this space;
in some cases it rises as high as the artery, and has even been seen to
mpany that vessel behind the Scalenus anterior. The brachial plexus of
es lies partly above and partly behind the artery, and in close contact
h it. Passing transversely behind the clavicle are the transverse scapular
sels; and running in the same direction, but at a slightly higher level are
transverse cervical artery and vein. The external jugular vein descends
hind the posterior border of the Sternocleidomastoideus, to terminate in the
clavian vein; it receives the transverse cervical and transverse scapular
s, which form a plexus in front of the third part of the subclavian artery,
occasionally it is joined by a small vein which crosses the clavicle from the
halic vein. The small nerve to the Subclavius also crosses this triangle
ort its middle, and some lymph-glands are contained within the space.

The Internal Carotid Artery

The **internal carotid artery** (fig. 668) supplies the greater part of the
rebral hemisphere, the eye and its appendages, and sends branches to the
rehead and nose. It begins at the bifurcation of the common carotid artery,
ends to the base of the skull, and enters the cranial cavity through the
rotid canal of the temporal bone. It then runs forward through the cavernous
s, lying in the carotid sulcus on the side of the body of the sphenoidal bone,
d ends below the anterior perforated substance of the brain by dividing into
e anterior and the middle cerebral arteries.

The internal carotid artery may be divided into four portions: cervical,
trous, cavernous, and cerebral.

The cervical portion.—This portion of the internal carotid artery begins at the
rcation of the common carotid artery, at the upper border of the thyreoid cartilage,
d ascends in front of the transverse processes of the upper three cervical vertebræ
the lower end of the carotid canal in the petrous portion of the temporal bone.
is comparatively superficial at its commencement, where it is contained in the
rotid triangle, and lies behind and lateral to the external carotid artery, overlapped
the Sternocleidomastoideus, and covered by the deep fascia, Platysma, and
n; it then passes beneath the parotid gland, being crossed by the hypoglossal
rve, the Digastricus and Stylohyoideus, and the occipital and posterior auricular
teries. Higher up, it is separated from the external carotid artery by the
yloglossus and Stylopharyngeus, the tip of the styloid process and the stylo-
oid ligament, the glossopharyngeal nerve and the pharyngeal branch of the
gus. It is in relation, *behind*, with the Longus capitis, the superior cervical
ngion of the sympathetic trunk, and the superior laryngeal nerve; *laterally*,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

with the internal jugular vein and vagus nerve, the nerve lying on posterior to the artery; *medially*, with the pharynx, superior laryngeal and ascending pharyngeal artery. At the base of the skull the glossopharyngeal, vagus, accessory, and hypoglossal nerves lie between the internal carotid and the internal jugular vein.

FIG. 668.—The right internal carotid and vertebral arteries.

The **petrous portion.**—When the internal carotid artery enters the carotid canal in the petrous portion of the temporal bone, it first ascends, then curves forwards and medialwards, and again ascends as it leaves the canal to enter the cranial cavity between the lingula and petrosal process of the sphenoidal bone. The artery lies at first in front of the cochlea and tympanic cavity; it is separated from

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

latter cavity and from the auditory tube by a thin, bony lamella, which is
deform in the young subject, and often partly absorbed in old age. Farther
ards it is separated from the semilunar ganglion by a thin plate of bone, which
the floor of the trigeminal impression and the roof of the horizontal portion of
rotid canal. Frequently this bony plate is more or less deficient, and then
anglion is separated from the artery by fibrous membrane. The artery is
ounded by a number of small veins and by the carotid plexus of nerves which
eived from the ascending branch of the superior cervical ganglion of the
pathetic trunk.

The cavernous portion of the internal carotid artery is situated in the cavernous
s, but is covered by the lining membrane of the sinus. It at first ascends
ards the posterior clinoid
ess, then passes forwards
the side of the body of the
noidal bone, and again
ves upwards on the medial
of the anterior clinoid
ess, and perforates the dura
r forming the roof of the

169).

FIG. 669.—An oblique section through the left cavernous sinus.

The cerebral portion.—After
ssing the dura mater on the medial side of the anterior clinoid process, the
nal carotid artery passes between the optic and oculomotor nerves to the
ior perforated substance at the medial end of the lateral cerebral fissure,
re it divides into the anterior and middle cerebral arteries.

Peculiarities.—The length of the internal carotid artery varies with the length of the
, and with the point of bifurcation of the common carotid. It arises occasionally
the arch of the aorta, and then has been found on the medial side of the external
id, as far as the larynx, where it crossed behind the latter vessel to reach its usual
ion. The course of the artery, instead of being straight, may be very tortuous. A
instances are recorded in which it was absent; in one of these the common carotid
passed up the neck, and gave off the branches normally arising from the external
id; the cranial portion of the internal carotid artery was replaced by two branches
e internal maxillary artery, which entered the skull through the foramen rotundum
foramen ovale, and joined to form a single vessel.

Applied Anatomy.—The cervical part of the internal carotid artery is very rarely
ded. Although the internal carotid lies about 2 cm. behind and lateral to the
, instances have occurred in which the artery has been wounded during the opera-
of excision of the tonsil, and fatal hæmorrhage has supervened. The incision for
ure of the cervical portion of the internal carotid should be made along the anterior
er of the Sternocleidomastoideus, from the angle of the mandible to the upper border
e thyreoid cartilage. The superficial structures being divided, and the Sternocleido-
deus defined and drawn backwards, the areolar tissue must be carefully separated,
the posterior belly of the Digastricus and the hypoglossal nerve sought as guides to
vessel. The external carotid should be drawn medialwards and the Digastricus
wards, and the aneurysm needle passed from the lateral to the medial side of the
id.

Obstruction of the internal carotid by embolism or thrombosis may give rise to
ms of cerebral anæmia and softening if the collateral circulation is ill-developed.
patient suffers from giddiness, with failure of the mental powers; and convulsions,
, or hemiplegia on the opposite side of the body, may be observed.
ligature of the internal carotid artery is not so effective as ligature of the common
id artery in diminishing the blood supply to the brain, because blood is conveyed to
brain through the anastomoses of the branches of the external carotid artery with the
ches of the petrous and cavernous parts of the internal carotid artery—especially
the ophthalmic artery.

Branches.—No branches arise from the cervical portion of the carotid artery. Those from the other portions are :

From the petrous portion	1. Caroticotympanic. 2. Pterygoid.
From the cavernous portion	3. Cavernous. 4. Hypophysial. 5. Semilunar. 6. Anterior meningeal. 7. Ophthalmic.
From the cerebral portion	8. Anterior cerebral. 9. Middle cerebral. 10. Posterior communicating. 11. Anterior chorioidal.

1. The **caroticotympanic branch** is small ; it enters the tympanic cavity by a foramen in the wall of the carotid canal, and anastomoses with the anterior tympanic branch of the internal maxillary artery, and with the stylomastoid artery.

2. A small, inconstant **pterygoid branch** passes into the pterygoid canal with the nerve of that canal, and anastomoses with a branch of the descending palatine artery.

3. The **cavernous branches** are numerous small vessels which supply the semilunar ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of them anastomose with branches of the middle meningeal artery.

4. The **hypophysial branches** are one or two minute vessels which supply the hypophysis.

5. The **semilunar branches** are small vessels supplying the semilunar ganglion.

6. The **anterior meningeal branch** is a minute branch which passes over the small wing of the sphenoid to supply the dura mater of the anterior cranial fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

7. The **ophthalmic artery** (fig. 670) arises from the internal carotid artery as that vessel emerges from the cavernous sinus, on the medial side of the anterior clinoid process ; it enters the orbital cavity through the optic foramen, below and lateral to the optic nerve. In the orbital cavity it runs for a short distance medial to the optic nerve and medial to the oculomotor, trochlear and abducent nerves, the ciliary ganglion, and the Rectus lateralis. It next crosses obliquely above the optic nerve and beneath the Rectus superior to reach the medial wall of the orbit. It then runs forwards between the Obliquus superior and the Rectus medialis, and at the medial end of the upper eyelid, divides into two branches, named the *frontal* and *dorsal nasal*. As the artery crosses the optic nerve it is accompanied by the nasociliary nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris ; the terminal part of the artery is accompanied by the infratrochlear nerve. In about 15 per cent. of subjects the ophthalmic artery crosses below the optic nerve.

The branches of the ophthalmic artery are :—

Central artery of the retina.	Long posterior ciliary.	Anterior meningeal.
Lacrimal.	Anterior ciliary.	Medial palpebral.
Muscular.	Supra-orbital.	Frontal.
Short posterior ciliary.	Posterior ethmoidal.	Dorsal nasal.
	Anterior ethmoidal.	

The **central artery of the retina**, the first and one of the smallest branches of the ophthalmic artery, arises from that vessel whilst it lies beneath the optic nerve. It runs for a short distance within the dural sheath of the optic nerve, and about 1·25 cm. behind the eyeball it pierces the inferomedial surface of the nerve, and runs forward in the substance of the nerve to the retina. Its mode of distribution is described with the anatomy of the eye.

The **lacrimal artery** arises from the ophthalmic artery close to the optic foramen, is one of its largest branches ; sometimes it is given off before the ophthalmic artery enters the orbit ; occasionally its place is taken by a branch of the middle meningeal artery (p. 618). It accompanies the lacrimal nerve along the upper border of the Rectus lateralis and supplies the lacrimal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva : of those supplying the eyelids, two are considerable size and are named the **lateral palpebral arteries** ; they run medialwards in the upper and lower lids respectively and anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two **zygomatic branches**, one of which passes through

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

zygomaticotemporal foramen to the temporal fossa, and anastomoses with the deep temporal arteries; another appears on the cheek through the zygomaticofacial foramen and anastomoses with the transverse facial artery. A **recurrent meningeal branch** passes forwards through the lateral part of the superior orbital fissure, and anastomoses with branch of the middle meningeal artery.

The muscular branches frequently spring from a common trunk. They consist of a superior and an inferior group, and most of them accompany the branches of the oculomotor nerve. The superior group supplies the Levator palpebræ superioris, Recti superior and lateralis, and Obliquus superior. The inferior group, more constantly present, is distributed to the Recti medialis et inferior, and the Obliquus inferior. This group gives branches of the anterior ciliary arteries. Additional muscular branches are derived from the lacrimal and supra-orbital arteries, or from the trunk of the ophthalmic artery.

The **ciliary arteries** are divisible into three groups, long and short posterior, and anterior. The **long posterior ciliary arteries**, two in number, pierce the posterior part of the sclera at a short distance from the entrance of the optic nerve, and run forwards, along either side of the eyeball, between the sclera and the choroid, to the ciliary body, where each divides into a superior and an inferior branch; these form, together with the anterior ciliary arteries, an arterial circle, the **circulus arteriosus major**, around the circumference of the iris; from the circulus arteriosus major numerous converging branches ramify in the substance of the iris to its pupillary margin, where they form a second arterial circle, the **circulus arteriosus iridis**. The **short posterior ciliary arteries**, about seven in number, pass forwards around the optic nerve to the posterior pole of the eyeball, and, after giving into from fifteen to twenty branches, pierce the sclera around the entrance of the optic nerve, and supply the vascular coat and the ciliary processes. The **anterior ciliary arteries** are derived from the muscular branches of the ophthalmic artery; they run to the front of the eyeball in company with the tendons of the Recti, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the sclerocorneal junction and join in the circulus arteriosus iridis.

Fig. 670.—The ophthalmic artery and its branches.

The **supra-orbital artery** leaves the ophthalmic artery as that vessel crosses the optic nerve. It ascends on the medial borders of the Rectus superior and Levator palpebræ superioris, and meeting the supra-orbital nerve accompanies it between the periosteum and the Levator palpebræ superioris to the supra-orbital foramen; passing through this foramen it divides into a superficial and a deep branch, which supply the skin, muscles, and pericranium of the forehead, anastomosing with the frontal artery, the frontal branch of the superficial temporal artery, and the artery of the opposite side. In the orbit it supplies twigs to the Rectus superior and the Levator palpebræ, and sends a branch across the pulley of the Obliquus superior, to the parts at the medial palpebral commissure. At the supra-orbital foramen it frequently sends a branch to the diploë.

The **posterior ethmoidal artery** runs through the posterior ethmoidal canal, supplies the posterior ethmoidal air-sinuses, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches which descend into the nasal cavity through the lamina cribrosa of the ethmoidal bone, to anastomose with branches of the sphenopalatine artery.

The **anterior ethmoidal artery** accompanies the anterior ethmoidal nerve through the anterior ethmoidal canal, supplies the anterior and middle ethmoidal and frontal air-sinuses, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches; the latter descend into the nasal cavity with the anterior ethmoidal nerve and, running along the groove on the inner surface of the nasal bone, supply twigs to the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

lateral wall and septum of the nose, and a terminal branch which appears on the of the nose between the nasal bone and the lateral nasal cartilage.

The **anterior meningeal artery** is a small branch which passes to the middle fossa through the superior orbital fissure and anastomoses with the middle and meningeal arteries.

The **medial palpebral arteries**, two in number, superior and inferior, arise ophthalmic artery below the pulley of the Obliquus superior. They descend lacrimal sac, and enter the eyelids where each divides into two branches lateralwards along the edges of the tarsal plates, thus forming two arches (a an inferior) in each eyelid. The superior palpebral artery anastomoses with orbital artery, and, at the lateral part of the eyelid, with the zygomatico-orbital

FIG. 671.—The arteries at the base of the brain.

of the temporal artery, and with the upper of the two lateral palpebral branches lacrimal artery. The inferior palpebral artery anastomoses at the lateral part eyelid with the lower of the two lateral palpebral branches of the lacrimal artery the transverse facial artery, and at the medial part of the eyelid with a twig fr angular artery; from this last anastomosis a branch passes to the nasolacrimal ramifying in its mucous membrane, as far as the inferior meatus of the nasal cavity.

The **frontal artery**, one of the terminal branches of the ophthalmic artery, lea orbit at its medial angle, with the supratrochlear nerve, and, ascending on the fore supplies the skin, muscles, and pericranium, anastomosing with the supra-orbital and with the artery of the opposite side.

The **dorsal nasal artery**, the other terminal branch of the ophthalmic artery, from the orbit between the trochlea of the Obliquus superior and the medial p ligament, and, after giving a twig to the upper part of the lacrimal sac, divides branches, one of which crosses the root of the nose, and anastomoses with the artery; the other runs along the dorsum of the nose, supplies its outer surface, and moses with the artery of the opposite side, and with the lateral nasal branch of the maxillary artery.

The **anterior cerebral artery** (figs. 671, 672, 673) arises from the internal carotid artery, at the medial end of the lateral cerebral fissure. It passes forwards and medialwards across the anterior perforated substance, above the optic nerve, to the commencement of the longitudinal fissure. Here it comes into close relation-

FIG. 672.—The lateral surface of the cerebral hemisphere, showing the areas supplied by the cerebral arteries. In this and the next figure the areas supplied by the anterior cerebral artery are coloured *blue*; those by the middle cerebral artery, *pink*; and those by the posterior cerebral artery, *yellow*.

with the opposite side and is joined to it by a short transverse (sometimes duplicated) named the anterior communicating artery. At this point, the two anterior cerebral arteries side by side in the longitudinal cerebral fissure, curving round the genu of the corpus callosum and running backwards along the upper surface of this structure to its posterior extremity, where they end by anastomosing with the posterior cerebral arteries.

The *anterior communicating artery* has an average length of about 4 mm. It connects the two anterior cerebral arteries across the commencement of the longitudinal fissure; in about 7 per cent. of subjects it is double. It gives off a few anteromedial ganglionic branches.

In its course the anterior cerebral artery gives off the following branches:

Anteromedial ganglionic.	Anterior.	Posterior.
Inferior.	Middle.	

The *anteromedial ganglionic branches* are a group of small arteries which arise near the commencement of the anterior cerebral artery; they pierce the anterior perforated substance and lamina terminalis, and supply the rostrum of the corpus callosum, the septum pellucidum, and the head of the caudate nucleus. The *inferior branches*, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and medial orbital gyrus. The *anterior branches* supply a part of the superior frontal gyrus, and send twigs over the superomedial border of the cerebral hemisphere to the superior and middle frontal gyri and upper part of the anterior central gyrus. The *middle branches* supply the corpus callosum, the cingulate gyrus, the medial surface of the superior frontal gyrus, and the upper part of the anterior central gyrus. The *posterior branches* supply the præcuneus and adjacent lateral surface of the hemisphere.

673.—The medial surface of the cerebral hemisphere, showing the areas supplied by the cerebral arteries (see description of fig. 672).

The **middle cerebral artery** (figs. 671, 672), the largest branch of the internal carotid artery, runs at first lateralwards in the lateral cerebral fissure and then forwards and upwards on the surface of the insula, where it divides into branches

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which are distributed to the insula and to the lateral surface of the hemisphere.

The branches of this vessel are the

Anterolateral ganglionic.	Ascending parietal.
Inferior lateral frontal.	Parietotemporal.
Ascending frontal.	Temporal.

The *anterolateral ganglionic branches* comprise a group of small arteries arise from the commencement of the middle cerebral artery and enter the substance of the brain through the anterior perforated substance.* They are arranged sets: one, the *medial striate*, ascends through the inner segments of the nucleus, and supplies it, the caudate nucleus, and the internal capsule; the the *lateral striate*, ascends through the outer segment of the lentiform nucleus supplies the caudate nucleus. One artery of this group is larger than the of special importance, as being the artery in the brain most frequently it has been termed by Charcot the '*artery of cerebral hæmorrhage*.' It between the lentiform nucleus and the external capsule, and ends in the nucleus. The *inferior lateral frontal* the inferior frontal gyrus and the part of the orbital surface of the lobe. The *ascending frontal* supplies anterior central gyrus. The *parietal* is distributed to the posterior gyrus and the lower part of the parietal lobule. The *parietotemporal* the supramarginal and angular gyri, posterior parts of the superior and temporal gyri. The *temporal branches* or three in number, are distributed lateral surface of the temporal lobe.

Fig. 674.—A diagram of the arteries at the base of the brain.

A.L. Anterolateral; A.M. Anteromedial; P.L. Posterolateral; P.M. Posteromedial ganglionic branches.

10. The **posterior communicating** (figs. 671, 674) runs backwards from internal carotid above the oculomotor and anastomoses with the posterior cerebral a branch of the basilar artery. usually a small vessel, but is occasionally large that the posterior cerebral may be sidered as arising from the internal rather than from the basilar. frequently larger on one side than other. From its posterior half arise off several small *posteromedial* branches, which, with similar vessels the posterior cerebral artery, pierce posterior perforated substance and the medial surfaces of the thalamus the walls of the third ventricle.

11. The **anterior chorioidal artery**, but constant branch, arises from the carotid, near the posterior communicating artery. Passing backwards and wards between the uncus and the cerebral peduncle, it enters the inferior of the lateral ventricle through the chorioidal fissure and ends in the plexus. It is distributed to the hippocampus, fimbria, tela chorioidea of the ventricle, and chorioid plexus.

The arterial circle of Willis.—A considerable part of the brain is supplied by the two vertebral arteries (p. 636), and a remarkable anastomosis, the *arterial circle of Willis*, exists between these vessels and the two internal carotid arteries. This circle is situated in the cisterna interpeduncularis the base of the brain, and encloses the optic chiasma and the structures interpeduncular fossa (p. 842). It is formed as follows: in front, the

* Consult an article on 'The basal arteries of the forebrain' by Joseph L. Shellshear, *of Anatomy*, vol. lv. 1920.

ior cerebral arteries are joined to one another by the anterior communicating artery; behind, the basilar artery (formed by the union of the bral arteries) divides into the two posterior cerebral arteries, each of is joined to the internal carotid artery of the same side by the posterior unicating artery (fig. 674).

THE ARTERIES OF THE BRAIN

The mode of distribution of the vessels of the brain has an important bearing upon considerable number of the pathological lesions which may occur in this part of the

us system.

The arteries which supply the brain give origin to two systems of vessels. One of these ned the **ganglionic system**, and its vessels supply the thalami and corpora striata; ther is the **cortical system**, and its vessels ramify in the pia mater and supply the r and subjacent brain-substance. These two systems are independent of one another do not communicate at any point of their peripheral distribution, and there is between ts supplied by them a borderland of diminished nutritive activity where, it is said, ion of the brain is especially liable to occur.

The **ganglionic system**.—All the vessels of this system are given off from the circle of (p. 630), or from the vessels close to it. They form six principal groups: (I) eromedial group, derived from the anterior cerebral and anterior communicating ies; (II) a **posteromedial group**, from the posterior cerebral and posterior communi- e arteries; (III and IV) right and left **anterolateral groups**, from the middle cerebral ies; and (V and VI) right and left **posterolateral groups**, from the posterior cerebral ies after they have wound round the cerebral peduncles. The vessels of the ganglionic m are larger than those of the cortical system, and are known as end arteries or al arteries—that is to say, vessels which from their origin to their termination r supply nor receive any anastomotic branch, so that, through any one vessel only ted area of the thalamus or corpus striatum can be injected.

The **cortical system**.—The vessels of this system are the terminal branches of the r, middle, and posterior cerebral arteries. They divide in the substance of the ter, give off branches which penetrate the brain-cortex perpendicularly, and are le into two classes, long and short. The **long or medullary arteries** pass through ey substance and penetrate the subjacent white substance to the depth of 3 or 4 cm., t intercommunicating otherwise than by very fine capillaries, and thus constitute ny independent small systems. The **short vessels** are confined to the cortex, where form with the long vessels a compact network in the middle zone of the grey sub- e, the outer and inner zones being sparingly supplied with blood. The vessels of ortical system are not so strictly 'terminal' as those of the ganglionic system, but approach this type very closely, so that injection of one area from the vessel of another though possible, is difficult, and only effected through vessels of small calibre; ction of one of these vessels may therefore produce softening in a limited area of the n cortex.

THE ARTERIES OF THE UPPER EXTREMITY

The artery which supplies the upper extremity runs as a single trunk as as the elbow; but is differently named, according to the regions verses. From its origin to the outer border of the first rib it is termed *clavian*; from the outer border of the first rib to the lower border of the on of the Teres major, it is named *axillary*; and from the lower border of Teres major to a point opposite the neck of the radius it is termed *brachial*.

The Subclavian Arteries (fig. 675)

The right **subclavian artery** arises from the innominate artery, the left m the arch of the aorta. The vessels, therefore, in the first parts of their ses, differ in length, direction, and relation with neighbouring structures. To facilitate description, each subclavian artery is divided into three parts; t extends from the origin of the vessel to the medial border of the us anterior, the second lies behind this muscle, and the third runs from lateral margin of the muscle to the outer border of the first rib, where it

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

becomes the axillary artery. The first portions of the two vessels dif one another in their origin, course and relations, and therefore require descriptions. The relations of the second and third parts are alm on the two sides of the neck.

The First Part of the Right Subclavian Artery (figs. 668,

The **first part** of the **right subclavian artery** arises from the inn artery, behind the upper part of the right sternoclavicular articulat passes upwards and lateralwards to the medial margin of the Scalenus It ascends, on an average, about 2 cm. above the clavicle, but the reaches varies considerably in different cases.

Relations.—*In front* of the artery are the skin, superficial fascia, Pl anterior supraclavicular nerves, deep fascia, the clavicular origin of the cleidomastoideus, the Sternohyoideus, and Sternothyreoideus. It is cr the internal jugular and vertebral veins, by the vagus nerve and the cardiac of the vagus and sympathetic; the subclavian loop of the sympathet encircles the vessel. The anterior jugular vein is directed lateralwards in the artery, but is separated from it by the Sternohyoideus and Sternothy *Below and behind* the artery are the pleura and the apex of the lung; beh artery are the sympathetic trunk, the Longus colli and the first thoracic ve The right recurrent nerve winds round the lower and posterior part of the

The First Part of the Left Subclavian Artery (figs. 655, 65

The **first part** of the **left subclavian artery** arises from the arch aorta, behind the left common carotid, and at the level of the upper bo the fourth thoracic vertebra; it ascends to the root of the neck an arches lateralwards to the medial border of the Scalenus anterior.

Relations.—It is in relation, *in front*, with the left vagus, cardiac, and nerves, the left common carotid artery, the left internal jugular and vertebr and the beginning of the left innominate vein, and is covered by the Sterno deus, Sternohyoideus, and Sternocleidomastoideus; *behind*, it is in relatio the œsophagus, thoracic duct, left recurrent nerve, inferior cervical gang the sympathetic trunk, and Longus colli; higher up, however, the œsopha thoracic duct lie to its right side, the latter ultimately arching over the v join the angle of union between the subclavian and internal jugular veins. to it are the œsophagus, trachea, thoracic duct, and left recurrent nerve; to it, the left pleura and lung.

The Second and Third Parts of the Subclavian Artery (fig.

The **second portion** of the subclavian artery lies behind the S anterior; it is very short, and forms the highest part of the arch des by the vessel.

Relations.—*In front* of it are the skin, superficial fascia, Platysma, cervical fascia, Sternocleidomastoideus, and Scalenus anterior. On the ri of the neck the phrenic nerve is separated from the second part of the art the Scalenus anterior, while on the left side it crosses the first part of the close to the medial edge of the muscle. *Behind* and *below* the vessel are the and lung; *above*, the brachial plexus of nerves. The subclavian vein lies and in front of the artery, separated from it by the Scalenus anterior.

The **third portion** of the subclavian artery runs downwards and la wards from the lateral margin of the Scalenus anterior to the outer bor the first rib, where it becomes the axillary artery. This is the most sup portion of the vessel, and is contained in the subclavian triangle (p. 62 portion of the vessel, and is contained in the subclavian triangle (p. 62

Relations.—*In front* of it are the skin, the superficial fascia, the Platysma supraclavicular nerves, and the deep cervical fascia. The external jugular crosses its medial part and receives the transverse scapular, transverse c and anterior jugular veins, which frequently form a plexus in front of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

and the veins, the nerve to the Subclavius descends in front of the artery. The vertical part of the artery lies behind the clavicle and the Subclavius, and is crossed by the transverse scapular vessels. The subclavian vein is in front of, and at a lower level than, the artery. The lowest trunk of the brachial plexus

FIG. 675.—A dissection of the right side of the neck, showing the carotid and subclavian arteries.

behind the artery and intervenes between it and the Scalenus medius. *Above*, to its *lateral side*, are the upper trunks of the brachial plexus, and the Omohyoideus. *Below*, it rests on the upper surface of the first rib.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height which they rise in the neck.

The right subclavian may arise from the innominate above or below the level of the sternoclavicular articulation. It may arise as a separate trunk from the arch of the aorta, and may then be either its first, second, third, or last branch; in the majority of cases it is the first or last. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it passes behind the right carotid artery; and when the last it arises from the left extremity of the arch, and ascends obliquely towards

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the right side, usually behind the trachea, œsophagus, and right carotid, sometimes the œsophagus and trachea, to the upper border of the first rib, whence it follows the course.

Occasionally the subclavian artery perforates the Scalenus anterior; very rarely passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus anterior. The artery may ascend as high as 4 cm. above the bone, or may only reach the level of the upper border of the bone.

The left subclavian is occasionally joined at its origin with the left carotid. It is deeply placed than the right subclavian in the first part of its course, and, as a rule, not reach quite as high a level in the neck.

The posterior border of the Sternocleidomastoideus corresponds closely to the border of the Scalenus anterior, so that the third portion of the artery, the part accessible for operation, lies immediately lateral to the posterior border of the cleidomastoideus.

Applied Anatomy.—An aneurysm may form on any part of the subclavian except the intrathoracic portion of the left vessel, which is said never to be the aneurysm. The most common site is the third portion (especially on the right). In this situation it may cause pressure on the brachial plexus, producing pain and ness in the arm and fingers, with loss of power or paralysis of the muscles of the Œdema of the arm may result from pressure on the subclavian vein. The jugular vein may become distended and varicose. The treatment is unsatisfactory proximal ligature cannot be undertaken with much chance of success; the best is excision of the sac. In aneurysm of the first portion of this artery there is of the head and face, with lividity, congestion of the brain, and semiconscious pressure on the innominate veins as they enter the chest; and spasmodic action Diaphragm from pressure on the phrenic nerve. The collateral circulation is that blocking of the subclavian artery by embolism or thrombosis often fails to to any striking signs or symptoms, beyond occasional pains in the neck and shoulder some degree of weakness and wasting in the muscles of the arm.

Compression of the subclavian artery may be required to control hæmorrhage can be effectually applied in one situation only, viz. where the artery passes over upper surface of the first rib. In order to compress the vessel in this situation shoulder should be depressed, and the surgeon grasping the side of the neck should with his thumb in the angle formed by the posterior border of the Sternocleidomastoideus with the upper border of the clavicle, downwards, backwards, and medialwards the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure made from before backwards, so as to compress the artery against the Scalenus and transverse process of the seventh cervical vertebra. In appropriate cases, liminary incision may be made through the cervical fascia, and the finger may be down directly upon the artery.

In cases of through-and-through gunshot wounds about the clavicle the formation an arteriovenous aneurysm, or direct communication between the subclavian artery some neighbouring vein, is not rare. This enables arterial blood at high pressure escape into the vein; the vein is distended thereby, with the production of a swelling that can be felt above or below the clavicle. In addition, a thrill can and a loud rushing murmur can be heard in the neighbourhood of the swelling. thrill and murmur are continuous, but more forcible during cardiac systole. Not quently these arteriovenous aneurysms call for relief by operation.

Ligature of the subclavian artery may be required in cases of wounds, or of aneurysm in the axilla, or in cases of aneurysm on the cardiac side of the point of ligature. vessel is also ligatured as a preliminary measure to the complete interscapulo-thoracic amputation of the upper extremity, in which case the transverse scapular and transverse cervical arteries may, if found, be ligatured at the same time, making the 'fore-quarter' amputation an almost bloodless procedure.

The third part of the artery is that which is most favourable for an operation account of its being comparatively superficial and most remote from the origin of large branches. In those cases where the clavicle is not displaced, this operation performed with comparative facility; but where the clavicle is pushed up by an aneurysmal tumour in the axilla, the artery lies at a great depth from the surface this materially increases the difficulty. Under these circumstances, it becomes a matter of importance to consider the height to which this vessel reaches above the bone. ordinary cases, its arch is about 1·25 cm. above the clavicle, occasionally as high 4 cm., and sometimes so low as to be on a level with its upper border. If the clavicle be displaced, these variations will necessarily make the operation more or less difficult according as the vessel is less or more accessible.

The procedure in the operation of tying the third portion of the subclavian artery 662, D) is as follows: The patient being placed on a table in the supine position, the head drawn over to the opposite side, and the shoulder depressed as much as possible the skin should be pulled downwards over the clavicle, and an incision made through upon that bone, from the anterior border of the Trapezius to the posterior border of Sternocleidomastoideus. The object in drawing the skin downwards is to avoid an

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

...ending the external jugular vein, which perforates the deep fascia above the clavicle, ...cannot be drawn downwards with the skin. The soft parts are allowed to glide up, ...the cervical fascia is divided; if the interval between the Trapezius and Sternocleido-...leus be insufficient, a portion of one or both may be divided. The external jugular ...will now be seen towards the medial side of the wound; this and the transverse ...ar and transverse cervical veins which end in it should be held aside. If any large ...ch at all in the way and exposed to injury, it should be tied in two places and divided. ...transverse scapular artery should be avoided, and the Omohyoideus held aside if ...ssary. In the space beneath this muscle a deep layer of fascia and some connective ...are divided, the lateral margin of the Scalenus anterior muscle felt for, and the ...being guided by it to the first rib, the pulsation of the subclavian artery will be ...as it passes over the rib. The sheath of the vessels having been opened, the aneurysm ...may then be passed around the artery from above downwards and medialwards so ...avoid including the lowest trunk of the brachial plexus which lies behind the artery ...the first rib. If the clavicle be so raised by the tumour that the application of the ...ture cannot be effected in this situation, the artery may be tied above the first rib, or ...behind the Scalenus anterior.

The second part of the subclavian artery, the portion which rises highest in the neck, ...been considered favourable for the application of the ligature when it is difficult to tie ...artery in the third part of its course. There are, however, many objections to the ...tion in this situation. It is necessary to divide the Scalenus anterior, upon which ...the phrenic nerve, and at the medial side of which is situated the internal jugular ...and a wound of either of these structures might lead to the most dangerous ...quences. Again, the artery is in contact, below, with the pleura, which must also ...ded; and, lastly, the proximity of so many of its large branches arising medial to ...point is a further objection to the operation. In cases, however, where the sac of an ...ry aneurysm encroaches on the neck, it may be necessary to divide the lateral half ...-thirds of the Scalenus anterior, so as to place the ligature on the vessel at a greater ...ce from the sac. The operation is performed exactly in the same way as a ligature ...the third portion, until the Scalenus anterior is exposed, when it is to be divided on ...tior (never to a greater extent than its lateral two-thirds), and it immediately ...ts. This is therefore merely an extension of the operation for ligature of the third ...on of the vessel.

In those cases of aneurysm of the axillary or subclavian artery which encroach upon ...lateral portion of the Scalenus anterior to such an extent that a ligature cannot be ...ed in that situation, it may be deemed advisable, as a last resource, to tie the first ...on of the subclavian artery. On the left side, this operation is almost impracticable; ...great depth of the artery from the surface, its intimate relation with the pleura, and ...close proximity to the thoracic duct and to so many important veins and nerves, ...ent a series of difficulties which it is next to impossible to overcome. On the right ...the operation is practicable, the main difficulty being the smallness of the interval ...h usually exists between the commencement of the vessel and the origin of the ...ous branch. The operation is essentially similar to that described on p. 603 for ...ure of the innominate artery. The exact position of the vagus, recurrent, and ...nic nerves and the sympathetic trunk should be borne in mind, and the ligature ...ld be applied near the origin of the vertebral, in order to afford as much room as ...ble for the formation of a coagulum between the ligature and the origin of the vessel. ...ould be remembered that the right subclavian artery is occasionally deeply placed in ...first part of its course, when it arises from the left side of the aortic arch, and passes ...ch cases behind the œsophagus, or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery, the ...eral circulation is established mainly by three sets of vessels, thus described in ...section:

1. A posterior set, consisting of the transverse scapular artery and the descending ...ch of the transverse cervical branch of the subclavian, anastomosing with the sub-...ar from the axillary.

2. A medial set, produced by the connexion of the internal mammary on the one hand, ...the arteria intercostalis suprema and the lateral thoracic and subscapular arteries ...the other.

3. A middle or axillary set, consisting of a number of small vessels derived from ...ches of the subclavian and, passing through the axilla, terminating either in the ...ry artery, or some of its branches. This last set presented most conspicuously ...peculiar character of newly formed or, rather, dilated arteries, being excessively ...us, and forming a complete plexus.

The chief agent in the restoration of the axillary artery below the aneurysm was the ...capular artery, which communicated freely with the internal mammary, transverse ...ar, and descending ramus of the transverse cervical arteries of the subclavian, ...all of which it received so great an influx of blood as to dilate it to three times its ...ral size.*

* *Guy's Hospital Reports*, vol. i. 1836. Case of axillary aneurysm, in which Aston Key had ...the subclavian artery at the lateral edge of the Scalenus anterior, twelve years previously.

When a ligature is applied to the first part of the subclavian artery, the circulation is carried on by the following anastomoses: 1, between the inferior thyreoids; 2, the two vertebrals; 3, the internal mammary with the epigastric and the aortic intercostals; 4, the costocervical with the aortic 5, the a. profunda cervicalis with the descending branch of the occipital; 6, the branches of the thyreocervical trunk with the branches of the axillary; and 7, the branches of the axillary with the aortic intercostals.

Branches.—The branches of the subclavian artery are:

Vertebral.	Thyreocervical.
Internal mammary.	Costocervical.

On the left side of the neck all four branches generally rise from the portion of the artery; on the right side the costocervical trunk usually from the second portion. On both sides, the first three branches close together at the medial border of the Scalenus anterior.

1. The **vertebral artery** (fig. 668) arises from the upper and part of the first portion of the subclavian artery. It ascends through foramina in the transverse processes of the upper six cervical vertebræ behind the superior articular process of the atlas, enters the skull through foramen magnum, and, at the lower border of the pons, unites with the of the opposite side to form the basilar artery.

Relations.—The vertebral artery may be divided into four parts. The *part* runs upwards and backwards between the Longus colli and the Scalenus and behind the common carotid artery. In front of it are the internal jugular vertebral veins, and it is crossed by the inferior thyreoid artery; the left artery is crossed also by the thoracic duct. Behind it are the transverse the seventh cervical vertebra, the sympathetic trunk and its inferior cervical The *second part* ascends through the foramina transversaria of the upper six vertebræ, and is surrounded by a plexus of nerves derived from the inferior sympathetic ganglion, and by a plexus of veins which unite to form the vertebral vein at the lower part of the neck. It lies in front of the trunks of the nerves, and pursues an almost vertical course as far as the transverse the epistropheus, through which it runs upwards and lateralwards to the transversarium of the atlas. The *third part* issues from the latter the medial side of the Rectus capitis lateralis, and curves backwards behind superior articular process of the atlas, the anterior ramus of the first cervical being on its medial side; it then lies in the groove on the upper surface posterior arch of the atlas, and enters the vertebral canal by passing beneath the arched border of the posterior atlanto-occipital membrane. This part artery is covered by the Semispinalis capitis and is contained in the *triangle*, which is bounded by the Rectus capitis posterior major, the superior, and the Obliquus inferior. The posterior division of the first nerve lies between the artery and the posterior arch of the atlas. The *fourth* pierces the dura mater and the arachnoid membrane, ascends in front of the of the hypoglossal nerve, and inclines medialwards to the front of the oblongata, where, at the lower border of the pons, it unites with the vessel opposite side to form the basilar artery.

The branches of the vertebral artery may be divided into two sets—those off in the neck, and those within the cranium.

Cervical branches.	*Cranial branches.*
Spinal.	Meningeal.
Muscular.	Posterior spinal.
	Anterior spinal.
	Posterior inferior cerebellar.
	Medullary.

Spinal branches enter the vertebral canal through the intervertebral foramina and each divides into two branches. Of these, one passes along the roots of nerves to supply the medulla spinalis and its membranes, anastomosing with other arteries of the medulla spinalis; the other divides into an ascending

* The vertebral artery sometimes [illegible] the transverse process of the vertebra, and has been seen entering that of the seventh vertebra.

ascending branch, which unite with similar branches from the arteries above and below, so that two lateral anastomotic chains are formed on the posterior surfaces of the bodies of the vertebræ, near the attachment of the pedicles. From these anastomotic chains branches are supplied to the periosteum and the bodies of the vertebræ, and others communicate with similar branches from the opposite side and below, to form a central anastomotic chain on the posterior surfaces of the bodies of the vertebræ.

Muscular branches arise from the vertebral artery as it curves round the superior articular process of the atlas. They supply the deep muscles of the neck and anastomose with the occipital artery, and the ascending and deep cervical arteries.

One or two **meningeal branches** spring from the vertebral artery opposite the foramen magnum, ramify between the bone and dura mater in the cerebellar fossa, and supply the falx cerebelli.

The **posterior spinal artery** arises from the vertebral artery at the side of the medulla oblongata, but is frequently derived from the posterior cerebellar artery. It passes backwards, and then descends behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches, which arise from the vertebral, ascending cervical, intercostal and lumbar arteries, and enter the vertebral canal through the intervertebral foramina; by means of these it is continued on the lower part of the medulla spinalis, and to the cauda equina. Branches of the posterior spinal arteries form a free anastomosis round the posterior roots of the spinal nerves, and communicate with the vessels of the opposite side. Near the origin each posterior spinal artery gives off an ascending branch, which ends at the side of the fourth ventricle.

The **anterior spinal artery** is a small branch, which arises near the termination of the vertebral artery; it descends in front of the medulla oblongata and unites with its fellow of the opposite side near the level of the lower end of the olive of the medulla oblongata. The single trunk, thus formed, descends on the front of the medulla spinalis, and is reinforced by a succession of small branches which enter the vertebral canal through the intervertebral foramina; these branches are derived from the vertebral, the ascending cervical, intercostal, and lumbar arteries. They unite, by means of ascending and descending branches, to form a single anterior spinal artery, which extends as far as the lower part of the medulla spinalis, and is continued as a slender twig on the filum terminale. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane, and the substance of the medulla spinalis, and sends off branches at its lower part to be distributed to the cauda equina. Branches pass from the anterior spinal arteries and from the beginning of the trunk formed by their union to the medulla oblongata.

The **posterior inferior cerebellar artery** (fig. 671) is the largest branch of the vertebral artery, but is not infrequently absent. It arises near, and winds backwards round, the lower end of the olive of the medulla oblongata; it then ascends behind the roots of the glossopharyngeal and vagus nerves to the under surface of the cerebellum, where it divides into a medial and a lateral branch. The medial branch runs backwards to the notch between the hemispheres of the cerebellum, while the lateral supplies the under surface of the hemisphere, as far as its lateral border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches supply the medulla oblongata and the choroid plexus of the fourth ventricle. A branch of this artery ascends between the inferior lobe and the tonsil of the cerebellum to supply the dentate nucleus of the cerebellum (Shellshear*).

The **medullary arteries** are several minute vessels which spring from the vertebral and its branches, and are distributed to the medulla oblongata.

The **basilar artery** (figs. 671, 674), so named from its position at the base of the brain, is formed by the junction of the two vertebral arteries; it extends from the pons to the upper border of the pons, and is contained within the cisterna pontis. It lies in a shallow, median groove on the ventral surface of the pons. It is placed between the two abducent nerves at the lower border, and between the two oculomotor nerves at the upper border, of the pons, where it divides into the two posterior cerebral arteries.

Its branches, on either side, are the following :

Pontine.	Anterior inferior cerebellar.
Internal auditory.	Superior cerebellar.
	Posterior cerebral.

The **pontine branches** are a number of small vessels which come off from the and sides of the basilar artery, and supply the pons and adjacent parts of the

The **internal auditory artery,** a long slender branch, may arise from the part of the basilar artery, but is more often derived from the anterior inferior bellar artery; it accompanies the acoustic nerve through the internal meatus and is distributed to the internal ear.

The **anterior inferior cerebellar artery** arises from the lower part of the artery. It runs backwards and lateralwards, usually ventral to the abducens and then between the pons and the facial and acoustic nerves, to the anterior of the under surface of the cerebellum, where it anastomoses with the inferior cerebellar branch of the vertebral artery. A few branches are supplied the anterior inferior cerebellar artery to the lower and lateral parts of the pons sometimes to the upper part of the medulla oblongata.

The **superior cerebellar artery** arises near the termination of the basilar passes lateralwards immediately below the oculomotor nerve which separates from the posterior cerebral artery, winds round the cerebral peduncle close below the trochlear nerve, and, arriving at the upper surface of the cerebellum divides into branches which ramify in the pia mater and anastomose with of inferior cerebellar arteries. Branches are given to the pons, the pineal the anterior medullary velum, and the tela chorioidea of the third ventricle.

The **posterior cerebral artery** (figs. 671, 672, 673), frequently double, is than the superior cerebellar artery, from which it is separated near its origin the oculomotor nerve, and on the side of the mesencephalon by the trochlear Passing lateralwards, parallel to the superior cerebellar artery, and receiving posterior communicating branch from the internal carotid artery, it winds the cerebral peduncle, and reaches the tentorial surface of the cerebrum, where breaks up into branches for the supply of the temporal and occipital lobes.

The branches of the posterior cerebral artery are divided into two ganglionic and cortical :

Ganglionic	Posteromedial.	*Cortical*	Anterior temporal.
	Posterior chorioidal.		Posterior temporal.
	Posterolateral.		Calcarine.
			Parieto-occipital.

Ganglionic branches.—The *posteromedial ganglionic branches* (fig. 674) are small arteries which arise at the commencement of the posterior cerebral and these with similar branches from the posterior communicating, pierce the posterior perforated substance, and supply the medial surfaces of the thalami and the of the third ventricle. The *posterior chorioidal branches* run forwards beneath the splenium of the corpus callosum, supply the tela chorioidea of the third ventricle, and end in the chorioid plexus of the lateral ventricle. The *posterolateral ganglionic branches* are small arteries which arise from the posterior cerebral after it has turned round the cerebral peduncle ; they supply a considerable portion of the thalamus.

Cortical branches.—These are : the *anterior temporal,* distributed to the and the anterior part of the fusiform gyrus ; the *posterior temporal,* to the fusiform and the inferior temporal gyri ; the *calcarine,* to the cuneus, gyrus lingualis, the posterior part of the lateral surface of the occipital lobe ; and the *parieto-occipital,* to the cuneus and the præcuneus.

2. The **internal mammary artery** (fig. 676) arises from the under surface of the first portion of the subclavian artery, opposite the thyreocervical trunk. It descends behind the cartilages of the upper six ribs at a distance of 1·25 cm. from the lateral border of the sternum, and at the level of the sixth intercostal space divides into the *musculophrenic* and *superior epigastric* arteries.

* Consult an article on 'The arteries of the pons and medulla oblongata' by J. S. B. Stopford, *Journal of Anatomy,* vols. l., li.

Relations.—It runs at first downwards, forwards, and medialwards behind the sternal end of the clavicle, the internal jugular and innominate veins, and the first costal cartilage. As the artery enters the thorax, the phrenic nerve crosses obliquely from the lateral to the medial side, the nerve usually passing in front of the artery. Below the first costal cartilage it descends almost vertically to its

FIG. 676.—The left internal mammary artery.

of bifurcation. It is covered in front by the Pectoralis major, the cartilages upper six ribs and the intervening anterior intercostal membranes and Inter- s interni, and is crossed by the terminal portions of the upper six intercostal a. It is separated from the pleura, as far as the second or third costal cartilage, a strong layer of fascia; below this level, by the Transversus thoracis. It is companied by a chain of lymph-glands and a pair of veins: about the level of third costal cartilage the veins unite to form a single vessel, which runs medial the artery and ends in the innominate vein.

The branches of the internal mammary artery are:

Pericardiacophrenic.	Sternal.	Musculophrenic.
Anterior mediastinal.	Intercostal.	Superior epigastric.
Pericardial.	Perforating.	

The **pericardiacophrenic artery** (a. comes nervi phrenici) is a long slender which accompanies the phrenic nerve, between the pleura and pericardium Diaphragm; it gives branches to the pleura, pericardium and Diaphragm, and moses with the musculophrenic and inferior phrenic arteries.

The **anterior mediastinal arteries** are small vessels, distributed to the areolar and lymph-glands in the anterior mediastinal cavity, and to the remains of the

The **pericardial branches** supply the upper part of the anterior surface pericardium.

The **sternal branches** are distributed to the Transversus thoracis, and to the surface of the sternum.

The anterior mediastinal, pericardial, and sternal branches, together with from the pericardiacophrenic, anastomose with branches from the intercostal bronchial arteries, and form a **subpleural mediastinal plexus.**

The **intercostal branches** supply the upper five or six intercostal spaces. number in each space, they pass lateralwards, one lying near the lower margin of above, and the other near the upper margin of the rib below, and anastomose intercostal arteries from the aorta. They are at first situated between the pl the Intercostales interni, and then between the Intercostales interni et externi supply the Intercostales and send branches through the Intercostales externi Pectorales and the mamma.

The **perforating branches** emerge through the upper five or six intercostal They pierce the Pectoralis major, and curving lateralwards, supply that muscle skin. Those of the second, third, and fourth spaces give branches to the mamma during lactation are of large size.

The **musculophrenic artery** is directed obliquely downwards and lateral behind the cartilages of the false ribs; it perforates the Diaphragm at the or ninth costal cartilage, and ends, considerably reduced in size, opposite intercostal space. It gives off intercostal branches to the seventh, eighth ninth intercostal spaces; these diminish in size as the spaces decrease in length are distributed in a manner similar to the intercostals from the internal mam The musculophrenic also gives branches to the lower part of the pericardium Diaphragm, and the abdominal muscles.

The **superior epigastric artery** descends through the interval between the and xiphoid origins of the Diaphragm, and enters the sheath of the Rectus abd at first lying behind the muscle, and then perforating and supplying it anastomosing with the inferior epigastric artery from the external iliac. Branches perforate the sheath of the Rectus, and supply the muscles and skin of the abd and a small branch passes in front of the xiphoid process and anastomoses the artery of the opposite side. The superior epigastric artery also gives twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Applied Anatomy.—The internal mammary artery is liable to be wounded in of the chest-wall and in the operation of paracentesis pericardii (p. 577). It is easily reached by a transverse incision in the second intercostal space.

3. The **thyreocervical trunk** (thyreoid axis) (fig. 675), a short trunk, arises from the front of the first portion of the subclavian artery to the medial border of the Scalenus anterior, and divides almost immediately into three branches, the *inferior thyreoid*, *transverse scapular*, and *transverse cervical*.

The **inferior thyreoid artery** runs upwards in front of the vertebral artery Longus colli; it then turns medialwards behind the carotid sheath and its contents and also behind the sympathetic trunk, the middle cervical ganglion of which lies upon the vessel; it finally descends to the lower border of the lateral lobe of thyreoid gland. At a little distance below the gland the inferior thyreoid usually passes behind the recurrent nerve, but when the gland is reached the is often behind the branches of the artery.*

The branches of the inferior thyreoid are :

Muscular.	Inferior laryngeal.	Œsophageal.
Ascending cervical.	Tracheal.	Glandular.

The muscular branches supply the depressors of the hyoid bone, and the Longus colli, Rectus anterior, and Constrictor pharyngis inferior.

The ascending cervical artery is a small branch which arises from the inferior thyreoid artery as that vessel is passing behind the carotid sheath ; it ascends on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Rectus anterior and Longus capitis. It gives twigs to the muscles of the neck, and sends one or two spinal branches into the vertebral canal through the intervertebral foramina to be distributed to the medulla spinalis and its membranes, and to the bodies of the vertebræ, in the same manner as the spinal branches from the vertebral artery. It anastomoses with the vertebral, ascending pharyngeal and occipital arteries.

The inferior laryngeal artery ascends upon the trachea in company with the recurrent nerve ; it enters the larynx under the lower border of the Constrictor pharyngis inferior, and supplies its muscles and mucous membrane, anastomosing with the artery from the opposite side, and with the superior laryngeal branch of the superior thyreoid artery.

The tracheal branches are distributed to the trachea, and anastomose below with the bronchial arteries.

The œsophageal branches supply the œsophagus, and anastomose with the œsophageal branches of the thoracic aorta.

The glandular branches consist of an inferior and an ascending branch ; they are distributed to the posterior and inferior parts of the thyreoid gland, and anastomose with the superior thyreoid artery and with the opposite inferior thyreoid artery ; the ascending branch supplies the superior parathyreoid gland.

The **transverse scapular artery** (suprascapular artery) (fig. 675) passes at first outwards and lateralwards across the Scalenus anterior and phrenic nerve, under cover of the Sternocleidomastoideus ; it then crosses the subclavian artery and the brachial plexus, and runs upward and parallel with the Clavicle and Subclavius, and beneath the inferior belly of the Omohyoideus, to the superior border of the scapula ; here it passes over (occasionally under) the superior transverse ligament which separates it from the suprascapular nerve, and enters the supraspinatous fossa (fig. 677). In this situation it lies on the bone, and supplies branches to the Supraspinatus. It then descends behind the neck of the scapula, through the great scapular notch and beneath the inferior transverse ligament, to reach the deep surface of the Infraspinatus, where it anastomoses with the scapular circumflex artery and the descending branch of the transverse cervical artery. Besides distributing branches to the Sternocleidomastoideus, Subclavius, and neighbouring muscles, it gives off a *suprasternal branch*, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest ; and an *acromial branch*, which pierces the Trapezius and supplies the skin over the acromion, anastomosing with the thoraco-acromial artery. As the transverse scapular artery passes over the superior transverse ligament of the scapula, it sends a branch into the subscapular fossa, where it ramifies beneath the Subscapularis, and anastomoses with the subscapular artery and with the descending branch of the transverse cervical artery. The transverse scapular artery also sends articular branches to the

FIG. 677.—The right scapular and circumflex arteries.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

acromioclavicular and shoulder-joints, and nutrient arteries to the cla[illegible] scapula. Occasionally the transverse scapular artery arises from the third [illegible] the subclavian artery.

The **transverse cervical artery** (a. transversa colli) (fig 675) lies at a hig[illegible] than the transverse scapular artery; it crosses in front of the phrenic [illegible] the Scaleni, and in front of or between the divisions of the brachial plex[illegible] covered by the Platysma and Sternocleidomastoideus. It passes behind [illegible] hyoideus and runs transversely above the inferior belly of that muscle [illegible] anterior margin of the Levator scapulæ, where it divides into an ascendi[illegible] descending branch.

The *ascending branch* (superficial cervical artery) ascends beneath the [illegible] part of the Trapezius, distributing branches to it and to the neighbouring [illegible] and lymph-glands in the neck, and anastomosing with the superficial bran[illegible] ramus descendens of the occipital artery.

The *descending branch* (posterior scapular artery) (fig. 677) passes bene[illegible] Levator scapulæ to the medial angle of the scapula, and then descends [illegible] cover of the Rhomboidei along the vertebral border of the scapula as fa[illegible] inferior angle of the bone. It supplies branches to the Rhomboidei, Le[illegible] dorsi and Trapezius, and anastomoses with the transverse scapular and sub[illegible] arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—Frequently the ascending branch (superficial cervical artery) [illegible] directly from the thyreocervical trunk, and the descending branch (posterior [illegible] artery) from the third, more rarely from the second, part of the subclavian.

4. The **costocervical artery** (superior intercostal artery) (fig. 668) [illegible] from the posterior aspect of the second part of the subclavian artery o[illegible] right side, but from the first part of the artery on the left side. It [illegible] backwards above the cupula of the pleura to the neck of the first rib, and d[illegible] into the arteria intercostalis suprema and the arteria cervicalis profun[illegible]

The **arteria intercostalis suprema** descends behind the pleura in front [illegible] necks of the first and second ribs, and anastomoses with the first aortic inte[illegible] artery. As it crosses the neck of the first rib it is medial to the anterior [illegible] of the first thoracic nerve, and lateral to the first thoracic ganglion of the sympa[illegible] trunk. In the first intercostal space, it gives off a branch which is distr[illegible] in a manner similar to the distribution of the aortic intercostals. The bran[illegible] the second intercostal space usually joins with one from the first aortic inte[illegible] artery; this branch is not constant, but is more commonly found on the [illegible] side; when absent, its place is supplied by an intercostal branch from the aor[illegible]

The **arteria cervicalis profunda** arises, in most cases, from the costocervical [illegible] and is analogous to the posterior branch of an aortic intercostal artery: occas[illegible] it is a separate branch from the subclavian artery. Passing backwards abo[illegible] eighth cervical nerve and between the transverse process of the seventh ce[illegible] vertebra and the neck of the first rib, it ascends on the back of the neck, bet[illegible] the Semispinales capitis et colli, as high as the second cervical vertebra, sup[illegible] the adjacent muscles, and anastomosing with the deep division of the ramus de[illegible] dens of the occipital artery (p. 615) and with branches of the vertebral artery [illegible] gives off a spinal twig which enters the vertebral canal through the foramen bet[illegible] the seventh cervical and first thoracic vertebræ.

The Axilla

The **axilla** is a pyramidal space, situated between the upper part o[illegible] lateral wall of the chest and the upper part of the medial side of the arm.

The *apex* of the axilla is directed upwards towards the root of the n[illegible] and corresponds to the interval between the outer border of the first [illegible] the superior border of the scapula, and the posterior surface of the clav[illegible] through it the axillary vessels and nerves enter the space from the neck. [illegible] *base*, directed downwards, is broad at the chest but narrow and pointe[illegible] the arm; it is formed by the skin and a thick layer of fascia, the *axillary f*[illegible] extending between the lower border of the Pectoralis major in front, and [illegible] lower border of the Latissimus dorsi behind. The *anterior wall* is formed [illegible] the Pectorales major et minor, the former covering the whole of this [illegible]

Digitized by Arya Samaj Foundation Chennai and eGangotri

latter only its central part. The space between the upper border of the oralis minor and the clavicle is occupied by the coracoclavicular fascia coracoid membrane). The *posterior wall* is formed by the Subscapularis the Teres major and Latissimus dorsi below. On the *medial side* are st four ribs with their corresponding Intercostales, and the upper part Serratus anterior. On the *lateral side*, where the anterior and posterior converge, the space is narrow, and bounded by the humerus, the Coraco-

The axilla contains the axillary vessels, the infraclavicular part of the chialis, and the Biceps brachii.

chial plexus of nerves, with its branches, the lateral branches of some of the rcostal nerves, and a large number of lymph-glands, together with a quantity fat and loose areolar tissue. The axillary vessels and the brachial plexus nerves run from the apex to the base along the lateral wall of the axilla; are placed nearer to the anterior than to the posterior wall, the axillary lying to the thoracic side of the axillary artery and partially concealing The thoracic branches of the axillary artery are in contact with the ratorales, and along the lower margin of the Pectoralis minor the lateral racic artery passes to the side of the thorax. The subscapular vessels and ves descend on the posterior wall in contact with the lower margin of the scapularis; the scapular circumflex vessels wind round the axillary border scapula, and the posterior humeral circumflex vessels and the axillary curve backwards close to the neck of the humerus. No vessel of any portance exists along the medial or thoracic side, the upper part of the being crossed merely by a few small branches from the highest thoracic ery. The long thoracic nerve descends on the surface of the Serratus anterior, which it is distributed; and the intercostobrachial nerve perforates the er and anterior part of this wall, and passes across the axilla to the medial of the arm.

The position and arrangement of the lymph-glands are described on 758 to 760.

Applied Anatomy.—The axilla is a space of considerable surgical importance. Its sels and nerves may be the seat of injury or disease: its lymph-glands may require ment; its loose connective tissue may be readily infiltrated with blood or inflamma- y exudation. Moreover, its base is covered by thin skin, which is well supplied with aceous and sweat glands, and is frequently the seat of small abscesses and boils.

Penetrating wounds in the axilla are sometimes accompanied by extensive hæmor- ge, either from wound of the main vessels, or of one of the large branches of the illary artery, e.g. the lateral thoracic or the subscapular. Where the blood cannot find easy exit it collects in the space and forms a large swelling which projects in the floor the axilla and also bulges forwards the Pectoralis major. The treatment consists in ly opening up the cavity, searching for and securing the bleeding vessel.

When suppuration occurs in the axilla, the arrangement of the fasciæ plays a very portant part in the direction which the pus takes. As described on p. 498, the coraco- ricular fascia, after covering the space between the clavicle and the upper border of Pectoralis minor, splits to enclose this muscle, and at its lower border is incorporated th the axillary fascia at the anterior fold of the axilla. Suppuration may take place her superficial to or beneath this layer of fascia; that is, either between the Pectorales behind the Pectoralis minor; in the former case, the abscess would point either at e border of the anterior axillary fold, or in the groove between the Deltoideus and the toralis major; in the latter, the pus would have a tendency to surround the vessels d nerves, and ascend into the neck, that being the direction in which there is least stance. Its progress towards the surface is prevented by the axillary fascia; its gress backwards, by the insertion of the Serratus anterior; forwards, by the coraco- ricular fascia; medialwards, by the wall of the thorax; and lateralwards, by the upper ch. The pus in these cases, after extending into the neck, has been known to spread ough the superior opening of the thorax into the mediastinal cavity. Instances have en recorded where the pus found its way along the vessels into the arm.

When opening an axillary abscess, the knife should be entered in the floor of the a, midway between the anterior and posterior margins and near the thoracic side of space so as to avoid the lateral thoracic, subscapular, and axillary vessels which are ntact respectively with the anterior, posterior and lateral walls of the axilla. After incision has been made through the skin and fascia, it is well to use a director and ding forceps in the manner directed by Hilton.

The relations of the vessels and nerves in the several parts of the axilla are important, y it is the universal plan to remove the lymph-glands from the axilla in operating for cer of the breast. In performing such an operation, it is necessary to proceed with

much caution in the direction of the lateral wall and apex of the space, axillary vessels are in danger of being wounded. The thoracodorsal nerve to simus dorsi and the long thoracic nerve to the Serratus anterior must be isolated. In clearing out the axilla, the axillary vein should first be defined up to the apex of the space by means of a director. In order to do this the major, together with the whole of the Pectoralis minor, must be divided and by which means the surgeon is enabled to clear out the axillary cavity more When the apex of the space is reached all the fat and the lymph-glands must removed and the whole axilla cleared by separating the tissues from above from the vessels, and from the medial and posterior walls, so that when the completed the axilla is emptied of all its contents except the main vessels and

The Axillary Artery (fig. 678)

The axillary artery, the continuation of the subclavian artery, the outer border of the first rib, and ends at the lower border of the major, beyond which the artery takes the name of brachial. Its varies with the position of the limb: thus the vessel is nearly straight

Fig. 678.—The right axillary artery and its branches.

the arm is directed at right angles with the trunk, concave upwards when arm is elevated above this, and convex upwards and lateralwards when arm lies by the side of the trunk. The first part of the artery is deeply situ but its terminal part is superficial and is covered only by the skin and fas The Pectoralis minor crosses the vessel and divides it into three portions first part is proximal to, the second behind, and the third distal to the mus

...us anterior, the long thoracic and medial anterior thoracic nerves, and the ...al cord of the brachial plexus. On the *lateral side* of the artery are the lateral ...posterior cords of the brachial plexus; on the *medial side* is the axillary vein ...overlaps the artery. The first part of the artery is enclosed, together with ...illary vein and the brachial plexus, in a fibrous sheath, the *axillary sheath*, ...uous above with the deep cervical fascia.

Relations of the second part.—In front of the second part of the axillary artery ...the skin, superficial and deep fascia, and the Pectorales major et minor; *behind* ...the posterior cord of the brachial plexus and some areolar tissue which inter- ...between it and the Subscapularis; on the *medial side* is the axillary vein, ...rated from the artery by the medial cord of the brachial plexus and the medial ...rior thoracic nerve; on the *lateral side* is the lateral cord of the brachial plexus. ...cords of the brachial plexus thus surround the second part of the artery on ...sides, and separate it from direct contact with the vein and adjacent muscles.

Relations of the third part.—The third part of the axillary artery extends from ...lower border of the Pectoralis minor to the lower border of the Teres major. ...upper part is covered *in front* by the lower part of the Pectoralis major; its ...er part by the skin and fasciæ only. *Behind* it are the lower part of the Sub- ...ularis and the tendons of the Latissimus dorsi and Teres major. On its *lateral* ...is the Coracobrachialis, and on its *medial side*, the axillary vein. The nerves ...brachial plexus bear the following relations to this part of the artery; on ...*lateral side* are the lateral head and the trunk of the median, and, for a short ...ance the musculocutaneous; on the *medial side* are the medial antibrachial ...aneous, ulnar, and medial brachial cutaneous nerves. The medial antibrachial ...aneous nerve lies between the artery and vein anteriorly, and the ulnar nerve ...ween the axillary artery and vein posteriorly; the medial brachial cutaneous ...e is on the medial side of the vein; *in front* is the medial head of the median ...e, and *behind*, the radial and axillary nerves, the latter only as far as the lower ...der of the Subscapularis.

Applied Anatomy.—Compression of the axillary artery may be required in the removal ...mours, or in amputation of the upper part of the arm. The only situation in which ...pression can be effectually made is in the lower part of its course; by pressing the ...y against the humerus in this situation, the circulation may be effectually arrested.

With the exception of the popliteal, the axillary artery is perhaps more frequently ...ated than any other artery in the body by violent movements, particularly in those ...es where its coats are diseased. It has occasionally been ruptured in attempts to reduce ...dislocations of the shoulder-joint, especially where the artery has become fixed to the ...sule of the joint. Aneurysm of the axillary artery sometimes occurs and is often ...matic in its origin.

Ligature of the axillary artery may be required in cases of aneurysm of the upper part ...the brachial, or as a distal operation for aneurysm of the subclavian.

Ligature of the *third part* of the axillary artery is easy, and may be performed as follows ...679, A): The arm is drawn from the side, the hand supinated, and an incision about ...n long made through the skin of the floor of the axilla, a little nearer to the anterior ...n to the posterior fold of the axilla. After dissecting through the areolar tissue and ...n, the median nerve and axillary vein are exposed; these are retracted and, the elbow ...ng bent so as relax the structures, the ligature is applied. This portion of the artery ...ccasionally crossed by a muscular slip, the *axillary arch* (p. 495), derived from the ...issimus dorsi.

The *first portion* of the axillary artery may be tied in cases of aneurysm encroaching ...ar upwards that a ligature cannot be applied to the lower part of the artery. Its ...formance is attended with much difficulty and danger. The student will remark that, ...this situation, it would be necessary to divide a thick muscle, and, after incising the ...coclavicular fascia, the artery would be exposed at the bottom of a more or less deep ...e, with the cephalic and axillary veins in such relation with it as must render the ...ation of a ligature to it particularly hazardous. Under such circumstances, it is ...easier and, at the same time, a more advisable operation, to tie the third part of the ...clavian artery. The first part of the axillary artery can be best secured by a curved ...ision with the convexity downwards from a point 1·25 cm. lateral to the sterno- ...ular joint to a point 1·25 cm. on the medial side of the coracoid process. The limb ...be well abducted, and the incision carried through the superficial structures, care ...g taken of the cephalic vein at the lateral end of the incision. The clavicular origin ...the Pectoralis major is then divided in the whole extent of the wound. The arm is ...brought to the side, and the upper edge of the Pectoralis minor defined and drawn ...wards. The coracoclavicular fascia is divided, and the axillary sheath exposed; ...is to be opened with especial care on account of the vein overlapping the artery. ...e needle should be passed from below, so as to avoid wounding the vein.

The *second portion* of the axillary artery may be tied through an incision the junction of the middle with the lateral one-third of the clavicle, and carried wards between the Deltoideus and the clavicular part of the Pectoralis major and junction of the anterior fold of the axilla with the upper arm. These two muscles separated and the Pectoralis minor divided. The artery must be clearly defined surrounded by the large nerve-trunks.

FIG. 679.—Dissections to show (A) the third part of the axillary artery, (B) brachial artery at the middle of the arm, and (C) the brachial artery at lower part of the arm.

Collateral Circulation.—If the axillary artery be tied above the origin of the acromial artery, the collateral circulation will be carried on by the same branches the ligature of the third part of the subclavian (p. 635), if at a lower point, between thoraco-acromial and the subscapular arteries, the latter vessel, by its free anastomosis with the transverse scapular and transverse cervical arteries, will become the chief in carrying on the circulation; the lateral thoracic artery, if it be below the ligature, materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the ligature be applied below the origin of the subscapular artery, it most probably also be below the origins of the two humeral circumflex arteries chief agents in restoring the circulation will then be the subscapular and the two humeral circumflex arteries anastomosing with the arteria profunda brachii.

The branches of the axillary artery are :

From first part 1. Highest thoracic. *From second part* { 2. Thoraco-acromial. 3. Lateral thoracic.

From third part { 4. Subscapular. 5. Anterior humeral circumflex. 6. Posterior humeral circumflex.

1. The **highest thoracic artery** (superior thoracic artery) (fig. 678) is a small vessel, which arises from the axillary artery near the lower border of the Subclavius muscle, but may take origin from the thoraco-acromial artery. Running forwards and medialwards along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies branches to the muscles, and to the thoracic wall, and anastomoses with the internal mammary and intercostal arteries.

2. The **thoraco-acromial artery** (thoracic axis) (fig. 678) is a short trunk which arises from the front of the axillary artery, its origin being overlapped by the upper edge of the Pectoralis minor. Passing forwards at the upper border of this muscle, it pierces the coracoclavicular fascia and divides into four branches, pectoral, acromial, clavicular, and deltoid. The *pectoral branch* descends between the two Pectorales, and is distributed to them and to the mamma, anastomoses with the intercostal branches of the internal mammary artery and with the lateral thoracic artery. The *acromial branch* runs lateralwards over the coracoid process and under the Deltoideus, to which it gives branches; it then pierces that muscle and ends on the acromion, where it anastomoses with branches of the transverse scapular, thoraco-acromial, and posterior humeral circumflex arteries.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

clavicular branch runs upwards and medialwards between the clavicular part of the Pectoralis major and the coracoclavicular fascia; it gives branches to the sterno-clavicular joint, and to the Subclavius. The *deltoid* or *humeral branch* often joins with the acromial branch; it crosses over the Pectoralis minor and runs with the cephalic vein between the Pectoralis major and Deltoideus, giving branches to the muscles.

The **lateral thoracic artery** (long thoracic artery) (fig. 678) follows the lower border of the Pectoralis minor to the side of the chest, supplies the Serratus anterior and the Pectorales, and sends branches to the axillary lymph-glands, and to the Subscapularis; it anastomoses with the internal mammary, subscapular, and intercostal arteries, and with the pectoral branch of the thoraco-acromial artery. In the female, the lateral thoracic artery is large, and gives off an *external mammary* branch which turns round the free edge of the Pectoralis major and supplies the mamma.

The **subscapular artery** (fig. 678), the largest branch of the axillary artery, arises from the lower border of the Subscapularis, which it follows to the inferior angle of the scapula, where it anastomoses with the lateral thoracic and intercostal arteries with the descending branch of the transverse cervical artery and ends in the surrounding muscles and adjacent part of the chest-wall. In the lower part of its course it is accompanied by the thoracodorsal nerve; about 2 in. from its origin it gives off the *scapular circumflex* artery.

Fig. 680.—The right scapular and circumflex arteries.

The **scapular circumflex** artery (arteria dorsalis scapulæ) is generally larger than the continuation of the subscapular. It curves round the axillary border of the scapula, traversing the triangular space between the Subscapularis above, the Teres major below, and the long head of the Triceps laterally (fig. 680); it enters the infraspinatous fossa under cover of the Teres minor, and anastomoses with the transverse scapular artery and the descending branch of the transverse cervical artery. It gives off two branches: one (*infrascapular*) enters the scapular fossa beneath the Subscapularis, which it supplies, and anastomoses with the transverse scapular artery and the descending branch of the transverse cervical artery; the other is continued along the axillary border of the scapula, between the Teres major and the Teres minor, and at the dorsal surface of the inferior angle anastomoses with the descending branch of the transverse cervical artery. In addition to these, small branches are distributed to the posterior part of the Deltoideus and the long head of the Triceps brachii, anastomosing with an ascending branch of the arteria profunda brachii.

The **anterior humeral circumflex artery** (fig. 680), a small artery, arises from the lateral side of the axillary artery at the lower border of the Subscapularis. It passes horizontally, beneath the Coracobrachialis and short head of the Biceps brachii, round the neck of the humerus. On reaching the intertubercular sulcus, it gives off a branch which ascends in the sulcus to supply the head of the humerus and the shoulder-joint. The trunk of the vessel is then continued onwards beneath the long head of the Biceps brachii and the Deltoideus, and anastomoses with the posterior humeral circumflex artery.

The **posterior humeral circumflex artery** (fig. 680), considerably larger than the anterior, arises from the axillary artery at the lower border of the Subscapularis,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and runs backwards with the axillary nerve through the quadrangular space by the Subscapularis, the Teres minor and the capsule of the shoulder-joint, the Teres major below, the long head of the Triceps brachii medially, and the neck of the humerus laterally. It winds round the neck of the humerus and tributes branches to the shoulder-joint, the Deltoideus, the Teretes major and the long and lateral heads of the Triceps brachii. It anastomoses anterior humeral circumflex, transverse scapular, thoraco-acromial, and brachii arteries.

Peculiarities.—The branches of the axillary artery vary considerably in subjects. One, named *alar thoracic*, and frequently derived from the second part artery, is distributed to the fat and the lymph-glands in the axilla. Occasionally subscapular, humeral circumflex, and profunda arteries arise from a common trunk; when this occurs the branches of the brachial plexus surround this trunk instead main vessel. Sometimes the axillary artery divides into the radial and ulnar and occasionally it gives origin to the volar interosseous artery of the forearm.

The Brachial Artery (figs. 681, 682, 683)

The **brachial artery** is a continuation of the axillary artery. It begins the distal border of the tendon of the Teres major, runs down the arm, ends about 1 cm. below the elbow joint by dividing into radial and ulnar arteries. At first it lies on the medial side of the humerus but, gradually passing to the front of the arm, is placed midway between the humeral epicondyles and the elbow.

Fig. 681.—The brachial artery.

Relations.—The artery is superficial throughout its entire course being covered with the skin and superficial and deep fascia; the lacertus fibrosus (bicipital fascia) lies in front of it opposite the elbow and separates it from the median cubital vein; the median nerve crosses the artery from the lateral to the medial side opposite the insertion of the Coracobrachialis. *Posteriorly*, it is separated from the long head of the Triceps brachii by the radial nerve and arteria profunda brachii. It lies successively on the medial head of the Triceps brachii, the insertion of the Coracobrachialis, and the Brachialis. *Laterally*, it is in relation above with the median nerve and the Coracobrachialis, below with the Biceps brachii, the muscles overlapping the artery to some extent. *Medially*, its upper half is in relation with the median, antibrachial cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on its medial side, but is separated from it in the lower part of the arm by the deep fascia. The artery is closely accompanied by two venæ comitantes which are connected at intervals by short transverse branches.

The Cubital Fossa

At the bend of the elbow the brachial artery sinks deeply into a triangular
al, the *cubital fossa*. The base of the triangle is represented by a line
ting the two humeral epicondyles; the sides are formed by the medial
of the Brachioradialis and the lateral margin of the Pronator teres; the
consists of the Brachialis and Supinator. This fossa contains the tendon
the Biceps brachii, the terminal part of the brachial artery, and its accom-
ying veins, the origins of the radial and ulnar arteries, and parts of the
dian and radial nerves. The brachial artery occupies the middle of the
and divides opposite the neck of the radius into the radial and ulnar
ries; it is covered, *in front*, by the skin, the superficial fascia, and the
dian cubital vein, the last being separated from the artery by the lacertus
rosus. *Behind* it is the Brachialis, which separates it from the elbow-joint.
e median nerve lies close to the medial side of the artery above, but is
rated from it below by the ulnar head of the Pronator teres. The tendon
the Biceps brachii is lateral to the artery; the radial nerve rests upon the
nator, and is concealed by the Brachioradialis.

Peculiarities.—The brachial artery, accompanied by the median nerve, may leave the
al border of the Biceps brachii, and descend towards the medial epicondyle of the
rus; in such cases it usually passes behind the *supracondylar process* of the humerus,
which a fibrous arch is in most cases thrown over the artery; it then runs beneath
ough the substance of the Pronator teres, to the bend of the elbow. This variation
considerable analogy with the normal condition of the artery in some of the carni-
, and has been referred to in the description of the humerus (p. 284*). Occasionally,
upper part of the artery splits into two trunks which reunite. Frequently it divides
higher level than usual, and the vessels concerned in this high division are three:
radial, ulnar, and interosseous arteries. Most frequently the radial is given off high
the other limb of the division consisting of the ulnar and interosseous; in some
ces the ulnar originates above the ordinary level, and the radial and interosseous
the other limb of the division; occasionally the interosseous arises high up.
Sometimes long slender vessels, termed *vasa aberrantia*, connect the brachial or the
ary artery with one or other of the arteries of the forearm. These vessels usually
the radial.
The brachial artery is occasionally concealed in some part of its course, by muscular
dinous slips derived from the Coracobrachialis, Biceps brachii, Brachialis, or
nator teres.

Applied Anatomy.—In spite of the fact that the brachial artery is very superficial
but little protected by surrounding parts, it is seldom wounded. This, no doubt, is
to its situation on the medial side of the arm, which is little exposed to injury.
Compression of the brachial artery is required in cases of amputation and some other
ations in the arm and forearm, and may be effected in almost any part of the course
the artery. If pressure be made in the upper part of the arm, it should be directed
rdwards; if in the lower part, backwards, as the artery lies on the medial side of
humerus above, and in front of it below. The most favourable situation is about
middle of the arm, where the artery lies on the tendon of the Coracobrachialis on the
al surface of the humerus.
Ligature of the brachial artery may be required in cases of wound of the vessel, and in
e cases of wound of the volar arch where an extensive dissection might be required to
e the bleeding point in the hand. It is also sometimes necessary in cases of
ysm of the brachial, radial, ulnar, or interosseous arteries. The artery may be
ed in any part of its course. The chief guides in determining its position are the
e markings produced by the medial margins of the Coracobrachialis and Biceps
hii, and the known course of the vessel; its pulsation should be carefully felt for
re any operation is performed, as the vessel occasionally deviates from its usual
ion. It is essential in applying a ligature to this vessel that the arm should be held
er from the side of the body, and supported only from the elbow, for if the arm be
ed to rest on any firm structure the Triceps brachii is pressed forwards and overlaps
vessel, thus making the operation much more difficult.
the upper third of the arm the brachial artery may be exposed in the following
er. The patient being placed supine, the limb should be raised from the side, and
and supinated. An incision about 5 cm. in length is made on the medial side of the
ochialis (fig. 682), and the subjacent fascia cautiously divided, so as to avoid
ing the medial antibrachial cutaneous nerve or basilic vein, as the latter some-
runs on the surface of the artery as high as the axilla. The fascia having been
d, it should be remembered that the ulnar nerve and the medial antibrachial
nerve lie on the medial side of the artery, the median nerve on the lateral side

In the case of a high division, the two arteries are usually placed side by side; and they are exposed in an operation, the surgeon should endeavour to ascertain, by alternately pressing on each vessel, which is connected with the wound or aneurysm, when a pulse may be applied accordingly; if pulsation or hæmorrhage ceases only when both are compressed, both must be tied.

In the middle of the arm the brachial artery may be exposed by making an incision along the medial margin of the Biceps brachii (fig. 679, B). The forearm is then bent so as to relax this muscle which should be drawn aside, and the fascia carefully divided, when the median nerve will be exposed lying upon (sometimes behind) the artery; the nerve being drawn medialwards and the muscle lateralwards, the artery should be separated from its accompanying veins and secured. In this situation the superior ulnar collateral artery (inferior profunda artery) may be mistaken for the main trunk, especially if enlarged

FIG. 684.—A transverse section through the arm, 2 cm. proximal to the medial epicondyle of the humerus.

on the collateral circulation having become established; this may be avoided by directing the incision towards the Biceps brachii, rather than towards the Triceps brachii.

The lower part of the brachial artery (fig. 679, C) is of interest on account of the relation it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic vein (median basilic vein) is the largest and most prominent, and consequently is one usually selected for the operation. This vein runs parallel with the brachial artery, from which it is separated by the lacertus fibrosus (bicipital fascia), and care should be taken, in opening the vein, not to carry the incision so deep as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the humeral circumflex and subscapular arteries anastomosing with ascending branches from the arteria profunda brachii. If the artery be tied below the origins of the arteria profunda brachii and the superior ulnar collateral artery, the circulation is maintained through the anastomoses around the elbow-joint (p. 652).

The branches of the brachial artery are:

1. Arteria profunda brachii
2. Nutrient.
3. Superior ulnar collateral.
4. Inferior ulnar collateral.
5. Muscular.

1. The **arteria profunda brachii** (superior profunda artery) (figs. 681, 683) is a large vessel which arises from the medial and posterior part of the brachial artery,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

just distal to the lower border of the Teres major. It follows closely the nerve, running at first backwards between the long and medial heads of the brachii, then along the sulcus for the radial nerve, where it is covered by the head of the Triceps brachii. Reaching the lateral side of the arm, it pierces the lateral intermuscular septum, and, descending between the Brachioradialis and Brachialis to the front of the lateral epicondyle of the humerus, ends by anastomosing with the radial recurrent artery. It gives branches to the Deltoideus and muscles between which it lies; it supplies an occasional *nutrient artery* which enters the humerus behind the deltoid tuberosity. A branch ascends between the medial and lateral heads of the Triceps brachii to anastomose with the posterior circumflex artery; a second *lateral branch* descends to the medial head of the Triceps brachii with the nerve; it supplies the Anconeus and assists in forming the anastomosis above the olecranon; a third *collateral branch* (posterior branch of superior profunda) runs behind the lateral intermuscular septum to the back of the lateral epicondyle of the humerus, where it anastomoses with the interosseous recurrent and the inferior ulnar collateral arteries.

Fig. 685.—A diagram of the arterial anastomosis around the elbow-joint.

2. The **nutrient artery** of the humerus arises about the middle of the arm; it enters the nutrient canal near the insertion of the Coracobrachialis, and is directed downwards.

3. The **superior ulnar collateral artery** (inferior profunda artery) (figs. 681, 683), of small size, arises from the brachial a little below the middle of the arm; it frequently springs from the common part of the arteria profunda brachii. It accompanies the ulnar nerve, pierces the medial intermuscular septum, descends between the medial epicondyle and the olecranon, and ends under the Flexor carpi ulnaris by anastomosing with the dorsal ulnar recurrent and inferior ulnar collateral arteries. It sometimes sends a branch in front of the medial epicondyle, to anastomose with the volar ulnar recurrent artery.

4. The **inferior ulnar collateral artery** (arteria anastomotica magna) (figs. 681, 683) arises about 5 cm. above the elbow. It passes medialwards upon the Brachialis and, piercing the medial intermuscular septum, winds round the back of the humerus between the Triceps brachii and the bone, forming, by its junction with the superior profunda brachii, an arch above the olecranon fossa. As the vessel lies on the Brachialis, it gives off branches which ascend to join the superior ulnar collateral artery; others descend in front of the medial epicondyle, to anastomose with the volar ulnar recurrent artery. Behind the medial epicondyle a branch anastomoses with the superior ulnar collateral and dorsal ulnar recurrent arteries.

5. The **muscular branches,** three or four in number, are distributed to the Coracobrachialis, Biceps brachii, and Brachialis.

The **anastomosis around the elbow-joint** (fig. 685.)—The vessels engaged in the anastomosis may be conveniently divided into those situated *in front* of, and those *behind* the medial and lateral epicondyles of the humerus. The branches anastomosing *in front* of the medial epicondyle are: the anterior branches of

successively upon the tendon of the Biceps brachii, the Supinator, the in the Pronator teres, the radial origin of the Flexor digitorum sublimis, the pollicis longus, the Pronator quadratus, and the lower end of the radius. upper one-third of its course it is placed between the Brachioradialis and the teres; in the lower two-thirds, between the tendons of the Brachioradialis Flexor carpi radialis. The superficial branch of the radial nerve is close lateral side of the middle one-third of the artery; and some filaments of the antibrachial cutaneous nerve run along the lower part of the artery as round the wrist. The artery is accompanied by a pair of venæ comitantes portion of the radial artery which lies in front of the lower end of the radius on the lateral side of the tendon of the Flexor carpi radialis is used clinically observations on the pulse.

Fig. 687.—A transverse section through the forearm at the level of the radial (bicipital) tuberosity.

(*b*) *At the wrist* (figs. 690, 691), the radial artery reaches the back of the wrist by passing between the radial collateral ligament of the wrist and the tendons of the Abductor pollicis longus and Extensor pollicis brevis. It then descends on the navicular and greater multangular bones, and before disappearing between the heads of the first Interosseus dorsalis is crossed by the tendon of the Extensor pollicis longus. In the interval between the two Extensores pollicis it is crossed by the origin of the cephalic vein, and by the digital rami of the superficial branch of the radial nerve, which go to the thumb and index finger.

(*c*) *In the hand* (fig. 689), the radial artery passes from the proximal end of the first interosseous space, between the heads of the first Interosseus dorsalis, transversely across the palm; it lies at first beneath the oblique part of the Adductor pollicis, then runs between the oblique and transverse parts, or through the transverse part, of that muscle, and, at the base of the fifth metacarpal bone, anastomoses with the deep volar branch from the ulnar artery, completing the *deep volar arch* (fig. 689).

Peculiarities.—In about 12 per cent. of subjects the origin of the radial artery is higher than usual; it then arises more often from the axillary or upper part of the brachial than from the lower part of the latter vessel. In the forearm it sometimes lies on the fascia instead of beneath it, and on the surface of the Brachioradialis instead of on its medial border; in turning round the wrist, it occasionally lies on, instead of beneath, the extensor tendons of the thumb.

Applied Anatomy.—The radial artery is much exposed to injury in its lower course and is frequently wounded; the injury may be followed by a traumatic aneurysm.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ligature of the radial artery is required in cases of wounds either of its trunk, or of its branches, or for aneurysm.

To tie the artery in the proximal one-third of the forearm (fig. 688, B), an incision 7 or long should be made through the skin, in a line drawn from the centre of the bend elbow to the front of the styloid process of the radius, avoiding the branches of dial antibrachial vein; when the fascia of the arm is divided, and the Brachioradialis aside, the artery will be exposed. The venæ comitantes should be separated from vessel and the ligature passed from the radial to the ulnar side.

In the middle one-third of the forearm the artery may be exposed by making an incision similar length on the medial border of the Brachioradialis. In this situation, the superpart of the radial nerve lies in close relation with the lateral side of the artery, and d be avoided.

In the distal one-third of the forearm (fig. 688, C) the artery is easily secured by dividing skin and fascia between the tendons of the Brachioradialis and Flexor carpi radialis. n operating on the cadaver, students are apt to forget how near to the surface the artery this situation.

FIG. 688.—Dissections to show the radial and median nerves, and the radial and ulnar arteries.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

In the forearm.	*At the wrist.*	*In the hand.*
Radial recurrent.	Dorsal carpal.	Princeps pollicis.
Muscular.	First dorsal metacarpal.	Volaris indicis radialis.
Volar carpal.		
Superficial volar.		

The **radial recurrent artery** arises immediately below the elbow. It passes between the branches of the radial nerve, and ascends beneath the Brachioradialis, lying on the Supinator and Brachialis; it supplies these muscles and the elbow-joint, and anastomoses with the anterior terminal part of the arteria profunda brachii.

The **muscular branches** are distributed to the muscles on the radial side of the forearm.

The **volar carpal branch** is a small vessel which arises near the lower border of the Pronator quadratus, and, running across the volar surface of the carpus, anastomoses under cover of the flexor tendons, with the volar carpal branch of the ulnar artery. This anastomosis is joined by a branch from the volar interosseous artery, and by recurrent branches from the deep volar arch, thus forming a *volar carpal network* which supplies the articulations of the wrist and carpus.

The **superficial volar branch** (fig. 686) arises from the radial artery, where this vessel is about to wind round the lateral side of the wrist. Running forwards, it passes through, occasionally over, the muscles of the ball of the thumb, which it supplies, and sometimes anastomoses with the terminal portion of the ulnar artery completing the superficial volar arch. This vessel varies considerably in size: usually it is very small, and ends in the muscles of the thumb; sometimes it is as large as the continuation of the radial artery.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The **dorsal carpal branch** (fig. 693) is a small vessel which arises beneath the extensor tendons of the thumb, and, running across the dorsal surface of the carpus under cover of the extensor tendons, anastomoses with the dorsal carpal branch of the ulnar artery, and with the volar and dorsal interosseous arteries, to form the *dorsal carpal network*. Arising from this network are three slender *dorsal metacarpal arteries*, which descend on the second, third, and fourth Interossei dorsales, and bifurcate into dorsal digital branches for the supply of the adjacent sides of the index, middle, ring, and little fingers; they anastomose with the proper digital branches of the superficial volar arch; near their origins they anastomose with the deep volar arch by the *superior perforating arteries*, and near their bifurcation with the common volar digital vessels of the superficial volar arch by the *inferior perforating arteries*.

The **first dorsal metacarpal artery** (fig. 693) arises just before the radial artery passes between the two heads of the first Interosseus dorsalis, and divides immediately into two branches which supply the adjacent sides of the thumb and index finger; the radial side of the thumb receives a branch directly from the radial artery.

The **arteria princeps pollicis** (fig. 689) arises from the radial artery as the latter turns medialwards to the deep part of the hand; it descends between the first Interosseus dorsalis and the oblique part of the Adductor pollicis, along the medial side of the metacarpal bone of the thumb to the base of the first phalanx, where it lies beneath the tendon of the Flexor pollicis longus and divides into two branches. These make their appearance between the medial and lateral insertions of the oblique part of the Adductor pollicis, and run along the sides of the thumb, forming on the volar surface of the last phalanx an arch, from which branches are distributed to the integument and subcutaneous tissue of the thumb.

The **arteria volaris indicis radialis** (fig. 689), frequently a branch of the proper part of the arteria princeps pollicis, descends between the first Interosseus dorsalis and the transverse part of the Adductor pollicis, and runs along the lateral side of the index finger to its extremity: it anastomoses with the proper digital artery supplying the medial side of the finger. At the lower border of the transverse part of the Adductor pollicis this vessel anastomoses with the arteria princeps pollicis, and gives a communicating branch to the superficial volar arch.

The arteria princeps pollicis and arteria volaris indicis radialis may spring by a common trunk which is named the *first volar metacarpal artery*.

The **deep volar arch** (deep palmar arch) (fig. 689) is formed by the anastomosis of the terminal part of the radial artery with the deep volar branch of the ulnar artery. It lies upon the proximal ends of the metacarpal bones and on the Interossei and is covered by the oblique part of the Adductor pollicis, the flexor tendons of the fingers, and the Lumbricales. Alongside of it, but running towards the lateral side of the hand, is the deep branch of the ulnar nerve.

The branches of the deep volar arch are: volar metacarpal, perforating, and recurrent.

The **volar metacarpal arteries** (fig. 689), three in number, arise from the concavity of the deep volar arch; they run distally upon the Interossei of the second, third and fourth spaces, and join, at the clefts of the fingers, the common digital branches of the superficial volar arch.

The **perforating branches,** three in number, pass backwards from the deep volar arch, through the second, third, and fourth interosseous spaces and between the heads of the corresponding Interossei dorsales, to anastomose with the dorsal metacarpal arteries.

The **recurrent branches** arise from the concavity of the deep volar arch, and ascend in front of the wrist, supply the intercarpal articulations, and end in the volar carpal network.

The Ulnar Artery (figs. 686, 689, 692)

The **ulnar artery**, the larger of the two terminal branches of the brachial artery, begins about 1 cm. below the bend of the elbow, and, passing obliquely downwards, reaches the medial side of the forearm at a point about midway between the elbow and the wrist. It then runs along the medial side of the wrist, crosses the transverse carpal ligament on the lateral side of the pisiform

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

and immediately beyond this bone divides into two branches, which into the formation of the superficial and deep volar arches.

Relations.—(*a*) *In the forearm.*—The *proximal half* of the vessel (figs. 686, 687) deeply seated, passing obliquely under cover of the Pronator teres, Flexor carpi alis, Palmaris longus, and xor digitorum sublimis to the dial side of the forearm, where is overlapped by the Flexor ris ulnaris; it lies upon the ris and the Flexor digi- orum profundus. The median ve is on the medial side of e artery for about 2·5 cm. and en crosses the vessel, but is arated from it by the ulnar d of the Pronator teres. The *ddle half* (figs. 686, 692) lies upon e Flexor digitorum profundus; is covered by the skin, super- al and deep fasciæ, and is ed between the Flexor carpi aris and Flexor digitorum limis.

It is accompanied by two ne comitantes, and is over- ped in its middle one-third the Flexor carpi ulnaris; the ar nerve lies on the medial de of the lower two-thirds of e artery, and the palmar aneous branch of this nerve ends on the distal part of the essel to the palm of the hand.

(*b*) *At the wrist* (figs. 689, 690, 691) the ulnar artery is covered the skin and the volar carpal ament, and lies upon the trans- rse carpal ligament. On its dial side are the pisiform bone d the ulnar nerve.

Peculiarities.—The ulnar artery ries in its origin in about 8 per nt. of cases; it frequently arises ove the elbow, the brachial being re often the source of origin than e axillary. When its origin is rmal, the course of the vessel is ndy changed. When the artery ves high up, it is usually super- al to the flexor muscles in the earm, lying commonly beneath e fascia more rarely between the scia and skin; the brachial artery ion gives off the common inter- seous artery, and the latter, the terior and posterior ulnar recur- nt arteries. Occasionally it is pcutaneous in the upper part of the forearm, and subaponeurotic in the lower

Fig. 689.—The right radial and ulnar arteries. Deep dissection.

When the ulnar artery is superficial there is some danger of its being wounded in opening the median cubital vein for the purpose of transfusing blood or injecting saline solution.

Applied Anatomy.—Ligature of the ulnar artery (fig. 688, D) in the upper one-half of the forearm is difficult as this part of the vessel is deeply seated beneath the superficial flexor muscles. An incision is to be made in the course of a line drawn from the front of the medial epicondyle of the humerus to the lateral side of the pisiform bone, so that

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the centre of the incision is three fingers' breadths below the medial epicondyle. T and superficial fascia having been divided, and the deep fascia exposed, the w which separates the Flexor carpi ulnaris from the other flexor muscles is to be so and the fascia incised in this line. On separating the Flexor carpi ulnaris from th muscles the ulnar nerve will be exposed lying on the Flexor digitorum profund must be drawn aside. The artery, accompanied by its venæ comitantes, lies b the nerve. In the middle and lower parts (fig. 688, E) of the forearm, the artery secured easily by making an incision on the radial side of the tendon of the Flex ulnaris: when the deep fascia is divided, and the tendon separated from the Flex torum sublimis, the artery and its venæ comitantes will be exposed, lying lateral ulnar nerve.

The branches of the ulnar artery may be arranged in the following gr

In the forearm
- Anterior recurrent.
- Posterior recurrent.
- Common interosseous.
- Muscular.

At the wrist
- Volar carpal.
- Dorsal carpal.

In the hand
- Deep volar.
- Superficial volar a

The **volar ulnar recurrent artery** (figs. 685, 689), a small branch, arises diately below the elbow-joint, runs upwards between the Brachialis and Pr teres, supplies twigs to those muscles, and, in front of the medial epico anastomoses with the superior and inferior ulnar collateral arteries.

Fig. 690.—A transverse section through the distal ends of the left radius and ulna. Superior aspect.

The **dorsal ulnar recurrent artery** (figs. 685, 689) is much larger, and arises what lower than the volar artery. It passes backwards and medialwards on Flexor digitorum profundus, behind the Flexor digitorum sublimis, and asc behind the medial epicondyle of the humerus. In the interval between this p and the olecranon, it lies beneath the Flexor carpi ulnaris, and ascends betwee heads of this muscle, in relation with the ulnar nerve; it supplies the neighb muscles and the elbow-joint, and anastomoses with the superior and inferior collateral and the interosseous recurrent arteries (fig. 693).

The **common interosseous artery** (fig. 689), about 1 cm. in length, arises imm ately below the tuberosity of the radius, and, passing backwards to the up border of the antibrachial interosseous membrane, divides into two branches, *volar* and *dorsal interosseous arteries*.

The **volar interosseous artery** (figs. 689, 692) descends on the volar surface of antibrachial interosseous membrane, accompanied by the volar interosseous br of the median nerve, and overlapped by the contiguous margins of the Fl digitorum profundus and Flexor pollicis longus; it gives off *muscular* branches, the *nutrient* arteries of the radius and ulna. At the upper border of the Pron quadratus it pierces the interosseous membrane and reaches the back of the forea

princeps pollicis. The arch passes across the palm, describing a curve, its convexity downwards.

Relations.—It lies upon the transverse carpal ligament, the Flexor digiti quinti of the flexor tendons, the Lumbricales, and the branches of the median nerve.

Branches.—The **common volar digital arteries** (fig. 686) arise from the convexity of the superficial volar arch and proceed downwards on the second, third, and fourth interosseoi, Each is joined by the corresponding volar metacarpal artery, and divides into a pair of *proper volar digital arteries* which run along the contiguous sides of the index, middle, ring, and little fingers, behind the corresponding digital arteries; they anastomose freely in the subcutaneous tissue of the finger tips and give smaller branches near the interphalangeal joints. Each gives off two dorsal branches which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the second and third phalanges, including the matrix of the nail. The proper volar digital artery for the medial side of the little finger arises from the ulnar artery under cover of the Palmaris brevis.

Applied Anatomy.—Wounds of the volar arches are always difficult to deal with. When the superficial arch is involved it is generally possible (enlarging the wound when necessary) to secure the vessel and tie it on both sides of the bleeding point; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of artery clips may be applied and left on for twenty-four or forty-eight hours. Failing this, the wound may be plugged with gauze and an outside dressing carefully bandaged on. The plug should remain undisturbed for three or four days. It is useless in these cases to ligature one of the arteries of the forearm alone, and simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hæmorrhage, it is expedient to apply a ligature to the brachial artery.

When an incision for deep-seated suppuration in the tendon-sheath is required, the position of the superficial arch must always be borne in mind, and the incisions placed either above or below it. The position of the common digital branches of the artery must be remembered, and the incisions made in front of the heads of the metacarpal bones and not between them.

THE ARTERIES OF THE TRUNK

The Descending Aorta

The descending **aorta** is divided into two portions, the *thoracic* and *abdominal*, in correspondence with the two great cavities in which it is situated.

The Thoracic Aorta (fig. 694)

The thoracic **aorta** is contained in the posterior mediastinal cavity. It begins at the lower border of the fourth thoracic vertebra where it is continuous with the aortic arch (p. 600), and ends in front of the lower border of the twelfth thoracic vertebra at the aortic hiatus in the Diaphragm. At its origin, it is situated on the left of the vertebral column; as it descends it approaches the median line, and at its termination lies in front of the column.

Relations.—It is in relation, *anteriorly*, from above downwards, with the root of the left lung, the pericardium, which separates it from the left atrium, the œsophagus, and the Diaphragm; *posteriorly*, with the vertebral column, the hemiazygos and accessory hemiazygos veins; on the *right side*, with the azygos vein and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying plexus of nerves, lies on the right side of the aorta above; but at the lower part of the thorax it is placed in front of the aorta, and, close to the Diaphragm, is situated on its left side.

Peculiarities.—The lumen of the aorta is occasionally found to be partly or completely obliterated, either at the aortic isthmus, or close to the point where the ductus arteriosus opens into it. This condition is known as *coarctation of the aorta*. It may be either congenital or acquired. In the former case the infant usually dies at or soon after birth. When acquired it is apparently due to an abnormal growth of the peculiar tissue of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the ductus into the aortic wall, giving rise to a simultaneous stenosis of both vessels. contracts after birth. This form of coarctation is compatible with many years of life, and leads to the establishment of an extensive collateral circulation to carry the aorta immediately below the stenosis by means of the following vessels—p internal mammary, anastomosing with the intercostal arteries, with the inferior of the abdominal aorta by means of the musculophrenic and pericardiacophrenic largely with the inferior epigastric. Secondly, the costocervical trunk, and

Fig. 694.—The heart and the thoracic aorta. Left lateral aspect.

anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyreoid, by means of a branch about the size of an ordinary radial, forming a communication with the aortic intercostal. Fourthly, the transverse cervical, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the clavian and axillary) going to the side of the chest enlarge, and anastomose freely with lateral branches of the intercostals. In a second case Wood describes the anastomoses in a somewhat similar manner, adding the remark, that 'the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis; while the supply to the lower extremities had passed through the internal mammary and epigastrics.

Applied Anatomy.—Aneurysm of the thoracic aorta most commonly extends backwards on the left side of the vertebral column and leads to absorption of the bodies of the vertebræ (but not of the intervertebral fibrocartilages) and of the ribs; pressure on the intercostal nerves may give rise to radiating pains in the left upper intercostal spaces; erosion of the vertebræ the aneurysm may compress the spinal nerve-roots or ultimately the medulla spinalis producing pains in the chest, back or loins, or paralysis below the site of the lesion; at the same time the aneurysm may project backwards under the skin as a pulsating swelling. If the aneurysm extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or may displace or compress the œsophagus, causing pain and difficulty of swallowing, and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the aneurysm extend to the right side, it may press upon the thoracic duct; it may burst into the pleural cavity, or into the lung; or it may open into the posterior mediastinal cavity. Pressure upon one of the bronchi, usually the left, will cause cough, and in time set up bronchiectasis; pressure on the left pulmonary plexus has been said to give rise to asthmatic attacks. Of late years, the diagnosis of thoracic aneurysm has been much facilitated by the employment of x-rays, by means of which the outline of the sac may be demonstrated.

The Branches of the Thoracic Aorta

Visceral { Pericardial. Bronchial. Œsophageal.

Parietal { Mediastinal. Superior phrenic. Intercostal. Subcostal.

The **pericardial branches** consist of a few small vessels which are distributed to the posterior surface of the pericardium.

The **bronchial arteries** vary in number, size, and origin. There is as a rule one left **bronchial artery,** which arises from the first aortic intercostal artery, or from the upper left bronchial artery. It runs on the posterior surface of the right bronchus, dividing and subdividing along the bronchial tubes, supplying them, the areolar tissue of the lung, and the bronchial lymph-glands; it also sends branches to the pericardium and the œsophagus. The **left bronchial arteries,** usually two in number, arise from the thoracic aorta, the upper opposite the fifth thoracic vertebra, and the lower just below the left bronchus. They run on the posterior surface of the left bronchus and have a distribution similar to that of the right bronchial artery.

The **œsophageal arteries,** four or five in number, arise from the front of the aorta, and pass obliquely downwards to the œsophagus; on this they form a vascular plexus which anastomoses above with the œsophageal branches of the inferior thyroid arteries, and below with ascending branches from the left inferior phrenic and left gastric arteries.

The **mediastinal branches** are numerous small vessels which supply the lymph-glands and loose areolar tissue in the posterior mediastinal cavity.

The **superior phrenic branches** are small, and arise from the lower part of the thoracic aorta; they are distributed to the posterior part of the upper surface of the Diaphragm, and anastomose with the musculophrenic and pericardiacophrenic arteries.

The **intercostal arteries.**—There are usually nine pairs of aortic intercostal arteries. They arise from the back of the aorta, and are distributed to the lower nine intercostal spaces, the first and second spaces being supplied by the arteria intercostalis suprema, a branch of the costocervical trunk of the subclavian artery (p. 642). The *right* aortic intercostal arteries are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they cross the bodies of the vertebræ behind the œsophagus, thoracic duct, and vena azygos, and are covered by the right lung and pleura. The *left* aortic intercostal arteries run backwards on the sides of the vertebræ and are covered by the left lung and pleura; the upper two vessels are crossed by the left superior intercostal vein, the lower vessels by the hemiazygos and accessory hemiazygos veins. The further course of the intercostal arteries is practically the same on both sides. Opposite the heads of the ribs the sympathetic trunk passes downwards in front of them, and the splanchnic nerves also descend in front of the lower arteries. Each artery then divides into an anterior and a posterior ramus.

Each *anterior ramus* (fig. 694) crosses its intercostal space obliquely towards the angle of the upper rib, and thence is continued forwards in the costal groove. It

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is placed at first between the pleura and the posterior intercostal membr[illegible] far as the angle of the rib; from this onward it runs between the Inter[illegible] externus et internus, and anastomoses in front with the intercostal branch[illegible] internal mammary or musculophrenic artery. Each artery is accompanied [illegible] vein and a nerve, the former being above and the latter below the artery, [illegible] the upper spaces, where the nerve is at first above the artery. The fir[illegible] intercostal artery anastomoses with the arteria intercostalis suprema, a[illegible] form the chief supply of the second intercostal space. The lower two in[illegible] arteries are continued anteriorly from the intercostal spaces into the ab[illegible] wall and anastomose with the subcostal, superior epigastric, and lumbar art[illegible]

Each anterior ramus gives off the following branches:

Collateral intercostal.	Lateral cutaneous.
Muscular.	Mammary.

The **collateral intercostal branch** comes off the anterior ramus of the intercostal [illegible] near the angle of the rib, and descends to the upper border of the rib below, along [illegible] it courses to anastomose with an intercostal branch of the internal mammary or m[illegible] phrenic artery. The collateral branches of the lower two anterior rami are so[illegible] absent; if present, they are small and end in the abdominal muscles.

Muscular branches are given to the Intercostales and Pectorales and to the S[illegible] anterior; they anastomose with the highest and lateral thoracic branches of the a[illegible] artery.

The **lateral cutaneous branches** accompany the lateral cutaneous branches of [illegible] thoracic nerves.

Mammary branches are given off by the vessels in the second, third, and f[illegible] spaces; they increase considerably in size during the period of lactation.

The **right bronchial artery** may arise from the first intercostal artery (p. 663).

Each *posterior ramus* runs backwards through a space which is bounded [illegible] and below by the necks of the ribs, medially by the body of a vertebra, and la[illegible] by an anterior costotransverse ligament. It gives off a *spinal branch* which [illegible] the vertebral canal through the intervertebral foramen, and is distributed [illegible] vertebræ and to the medulla spinalis and its membranes, anastomosing wi[illegible] spinal arteries above and below and with the artery of the opposite side. [illegible] posterior ramus then courses over the transverse process with the posterior di[illegible] of the thoracic nerve, supplies branches to the muscles of the back, and a cuta[illegible] branch which accompanies the cutaneous branch of the posterior division of [illegible] nerve.

Applied Anatomy.—The position of the anterior rami of the intercostal vessels [illegible] be borne in mind in performing the operation of paracentesis thoracis. The pu[illegible] should never be made nearer the middle line posteriorly than the angle of the rib, a[illegible] artery crosses the space medial to this point. In the lateral portion of the chest, [illegible] the puncture is usually made, the artery lies at the upper part of the intercostal [illegible] and therefore the puncture should be made just above the upper border of the rib [illegible] the lower boundary of the space.

The relation of the Diaphragm to the deep surface of the lower intercostal spaces [illegible] be remembered, otherwise the abdominal cavity may be opened inadvertently [illegible] making incisions in these spaces.

The **subcostal arteries,** so named because they lie below the last ribs, [illegible] series with the intercostal arteries. Each passes along the lower border of [illegible] twelfth rib behind the kidney and in front of the Quadratus lumborum. [illegible] is accompanied by the twelfth thoracic nerve. It then pierces the posterior [illegible] neurosis of the Transversus abdominis, and, passing forward between this [illegible] and the Obliquus internus, anastomoses with the superior epigastric, lower [illegible] costal, and lumbar arteries. Each subcostal artery gives off a posterior b[illegible] which has a distribution similar to the posterior ramus of an intercostal arte[illegible]

A small **aberrant artery** is sometimes found arising from the right side of the thor[illegible] aorta near the origin of the right bronchial. It passes upwards and to the right b[illegible] the trachea and the œsophagus, and may anastomose with the right arteria interc[illegible] suprema. It represents the remains of the right dorsal aorta (p. 121), and in a [illegible] proportion of cases is enlarged to form the first part of the right subclavian artery.

The Abdominal Aorta (fig. 695)

The abdominal aorta begins at the aortic hiatus of the Diaphragm, in front of the lower border of the body of the last thoracic vertebra, and, ending in front of the vertebral column, ends on the body of the fourth lumbar vertebra, a little to the left of the middle line, by dividing into the two common iliac arteries. It diminishes rapidly in size, in consequence of the large branches which arise from it.

Fig. 695.—The abdominal aorta and its branches.

Relations.—The abdominal aorta is covered, *anteriorly*, by the omental bursa and stomach, behind which are the branches of the cœliac artery and the cœliac plexus of nerves; below these, by the lienal vein, the pancreas, the left renal vein, the horizontal part of the duodenum, the root of the mesentery, the peritoneum and coils of the small intestine, and the aortic plexus of nerves. *Posteriorly*, it is separated from the lumbar vertebræ and intervertebral fibrocartilages by the anterior longitudinal ligament and the left lumbar veins. On the *right side* it is in relation above with the cisterna chyli, thoracic duct, azygos vein, and the right crus of the Diaphragm—the last separating it from the upper part of the inferior vena cava, and from the right cœliac ganglion; the inferior vena cava is in contact with the aorta below the level of the second lumbar vertebra. On the *left side* are

the left crus of the Diaphragm, the left cœliac ganglion, the ascending pa duodenum, some coils of the small intestine, the left sympathetic trunk, mesenteric and left testicular (spermatic) vessels, and the left ureter.

Applied Anatomy.—Aneurysm of the abdominal aorta occurs most frequen upper part close to and often involving the cœliac artery, since here the ves narrows after giving off several large branches, and its walls have lost the suppo higher up by the crura of the Diaphragm.

If the aneurysm enlarges forwards it forms a pulsating tumour in the p chondriac or epigastric regions; by pressure upwards at the same time it may with the movements of the Diaphragm and embarrass respiration, or may com œsophagus and produce dysphagia; pressure on the stomach and cœliac plexus to dyspepsia, while jaundice may follow pressure on the bile duct and duodenum, or albuminuria, hæmaturia and anuria pressure on the renal vessels and nerves; if the vena cava is compressed there may be œdema of the lower limbs. This form of may burst into the peritoneal cavity, behind the peritoneum, between the layers mesentery, or more rarely into the duodenum.

When an aneurysm of the abdominal aorta enlarges backwards it usually absorption of the bodies of the vertebræ, pain is invariably present and is usually kinds—a fixed and constant pain in the back, caused by the tumour eroding the and a sharp lancinating pain radiating to the loins, hypogastrium and buttocks branches of the lumbar nerves which are pressed on by the tumour.

Occlusion of the abdominal aorta by thrombosis or embolism is rare, but produ severe symptoms when it does occur. The patient complains of intense pain in the pallor of the legs, followed by coldness, lividity, paresis, paralysis, and finally are likely to succeed, death usually supervening within a fortnight.

The abdominal aorta has been tied in several cases, and although none of the permanently recovered, still, as one case lived forty-eight days, the possibility re-establishment of the circulation may be considered to be proved.

Collateral Circulation.—The collateral circulation would be carried on by the moses between the internal mammary and the inferior epigastric arteries; by the communication between the superior and inferior mesenteric arteries, if the ligature placed between these vessels; or by the anastomosis between the inferior mesenteric the internal pudendal arteries, when (as is more common) the point of ligature is the origin of the inferior mesenteric artery; and possibly by the anastomoses of the arteries with the branches of the hypogastric artery.

The Branches of the Abdominal Aorta (fig. 695)

The branches of the abdominal aorta may be divided into three visceral, parietal, and terminal.

Visceral branches.	*Parietal branches.*
Cœliac.	Inferior phrenic.
Superior mesenteric.	Lumbar.
Inferior mesenteric.	Middle sacral.
Middle suprarenal.	
Renal.	
Testicular (in the male).	*Terminal branches.*
Ovarian (in the female).	Common iliac.

Of the visceral branches, the cœliac artery and the superior and in mesenteric arteries are unpaired; the suprarenal, renal, testicular, and ov arteries are paired. Of the parietal branches, the middle sacral arter unpaired; the inferior phrenic and lumbar arteries are paired. The term branches are paired.

The Cœliac Artery (figs. 696, 697)

The **cœliac artery** is a thick trunk, about 1·25 cm. long, which a from the front of the aorta, just below the aortic hiatus of the Diaphra it passes nearly horizontally forwards above the pancreas and the lienal and divides into three large branches, (1) *left gastric*, (2) *hepatic*, and (3) or *splenic*; it occasionally gives off one of the inferior phrenic arteries.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Relations.—The cœliac artery is covered by the omental bursa and surrounded by the cœliac plexus of nerves. On its *right side* are the right cœliac ganglion, the right crus of the Diaphragm, and the caudate process of the liver, on its *left side* the left cœliac ganglion, the left crus of the Diaphragm, and the cardiac end of the stomach. *Below* it are the upper border of the pancreas and the lienal vein.

The **left gastric artery** (coronary artery) (fig. 696), the smallest branch of the cœliac artery, passes upwards and to the left, behind the omental bursa, to the cardiac orifice of the stomach. Here it gives off branches which

FIG. 696.—The cœliac artery and its branches; the liver has been raised, and the lesser omentum, the anterior layer of the greater omentum, and the posterior wall of the omental bursa removed.

spread on the œsophagus, and anastomose with the aortic œsophageal arteries; others supply the cardiac part of the stomach, and anastomose with branches of the lienal artery. The artery then turns forwards and downwards, and runs along the lesser curvature of the stomach to the pylorus, between the layers of the lesser omentum; it gives branches to both surfaces of the stomach and anastomoses with the right gastric artery.

2. The **hepatic artery** (fig. 696) is intermediate in size between the left gastric and lienal arteries. It is first directed forwards and to the right, to the upper margin of the superior part of the duodenum, forming the lower boundary of the epiploic foramen (foramen of Winslow). It then crosses in front of the portal vein, and ascends between the layers of the lesser omentum, and in front of the epiploic foramen, to the porta hepatis, where it divides into a right and a left branch, which supply the corresponding lobes of the liver, accompanying the ramifications of the portal vein and hepatic ducts. In the lesser omentum the hepatic artery lies in front of the portal vein, and on the

left of the bile-duct. The distribution of the hepatic artery within the liver is described with the anatomy of the liver, in the section on Splanchnology.

Its branches are:

Right gastric. Gastroduodenal. Cystic.

The **right gastric artery** (pyloric artery) (fig. 696) arises from the hepatic above the superior part of the duodenum; it descends in the lesser omentum to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches, and anastomosing with the left gastric artery.

FIG. 697.—The cœliac artery and its branches; the stomach has been raised, and the peritoneum removed.

The **gastroduodenal artery** (fig. 697) is a short but large branch, which descends near the pylorus, between the superior part of the duodenum and the neck of the pancreas, and divides at the lower border of the duodenum into two branches, the *right gastro-epiploic* and the *superior pancreaticoduodenal* arteries. Previous to its division it gives off two or three small branches to the pyloric end of the stomach and to the pancreas.

The **right gastro-epiploic artery** (figs. 696, 697), the larger terminal branch of the gastroduodenal artery, runs from right to left along the greater curvature of the stomach, between the layers of the greater omentum, and ends by anastomosing with the left gastro-epiploic branch of the lienal artery. Except at the pylorus, where it is in contact with the stomach, it lies about a finger's breadth from the greater curvature. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend in the greater omentum and anastomose with branches of the middle colic artery.

The **superior pancreaticoduodenal artery** (fig. 697) descends between the duodenum and the head of the pancreas. It supplies both these organs, and anastomoses

CC-0. In Public Domain. Panini Kanya Maha Vidyalaya Collection.

Digitized by Arya Samaj Foundation Chennai and eGangotri

the inferior pancreaticoduodenal branch of the superior mesenteric artery, with the pancreatic branches of the lienal artery.

The **cystic artery** (fig. 696), usually a branch of the right hepatic artery, passes wards and forwards along the neck of the gall-bladder, and divides into two es, one of which ramifies on the free surface, the other on the attached surface gall-bladder.

The **lienal or splenic artery** (figs. 696, 697), the largest branch of the e artery, is remarkable for the tortuosity of its course. Accompanied by lienal vein which lies below it, it passes horizontally to the left, behind stomach and the omental bursa of the peritoneum, and along the upper der of the pancreas; it then crosses in front of the left suprarenal gland the upper part of the left kidney, and, on arriving near the spleen, divides branches. Some of these branches enter the hilum of the spleen between two layers of the lienorenal ligament; some are given to the pancreas, e others pass to the greater curvature of the stomach between the ers of the gastrolienal ligament. Its branches are:

Short gastric.

Pancreatic.

Left gastro-epiploic.

The **pancreatic branches** (fig. 697) are numerous small vessels supplying the body il of the pancreas; they are derived from the lienal artery as it runs along pper border of the pancreas. One branch, larger than the rest, is sometimes n off near the tail of the pancreas; it runs from left to right near the posterior ce of the gland, following the course of the pancreatic duct, and is called the *ria pancreatica magna*. These vessels anastomose with the pancreatic branches the superior and inferior pancreaticoduodenal arteries.

The **short gastric arteries** (vasa brevia) (fig. 697) consist of from five to seven all branches which arise from the end of the lienal artery, and from its terminal sions. They pass from left to right, between the layers of the gastrolienal liga- , and are distributed to the greater curvature of the stomach, anastomosing h branches of the left gastric and left gastro-epiploic arteries.

The **left gastro-epiploic artery** (figs. 696, 697), the largest branch of the lienal ry, runs from left to right about a finger's breadth from the greater curvature the stomach, between the layers of the greater omentum, and anastomoses with right gastro-epiploic artery. It distributes several ascending branches to both aces of the stomach; others descend to supply the greater omentum and stomose with branches of the middle colic artery.
